INDEX TO VOLUME CXXVI.

- Abbott, S. W.** The bichloride of gold fraud, 75; recent progress in public hygiene, 311, 336.
- Abdomen.** The medico-legal aspect of intestinal surgery, Davis, J. D. S., 92.
- Abscess.** The disappearance of large phoss abscesses, Myers, H., 218.
- Achora, J. W.** Vindication of Dr. Sterling Pomeroy, 47.
- Acheson, H. E.** An improved apparatus for estimating urea, 446.
- Adams, J. F. A.** A case of biliary calculus, cholecystotomy, duodenal fistula, recovery, 55.
- Adams, S. S.** A case of death from *laryngismus stridulus* in incipient rachitis, 563.
- Advertising.** Advertisements for advertising, 327.
- Albuminuria.** Its relation to surgical operations, Long, J. W., 91; observations on albuminuria in scurifatia, Dudley, J. W., 128, 162; renal albuminuria not due to organic disease of the kidneys, Wood, E. S., 459, 476.
- Alcock, J. W.** The bichloride of gold fraud, Abbott, S. W., 75; drunkenness and crime, James, H., 324.
- Alcoholism.** A brief summary of the clinical history and treatment of 2,012 cases of alcoholism, of which 57 were maniacal, Latimer, T. S., 609.
- Allen, C. W.** On nomenclature of pediculosis, 440.
- Allen, C. W.** On the mechanism of the mammalian limb, 233.
- Allen, D. P.** The late manifestations of appendicitis and their treatment, 663.
- Almy murder trial, 475.**
- Alpecia areata.** Epidemic of alpecia areata in an orphan asylum during the year 1891, Putnam, C. F., 474.
- Ambrose, J. M.** The cardiac indications in the treatment of pneumonia, 661.
- Ambulance.** New London ambulance surgeons, 154.
- Anesthesia.** Local anesthesia, Scheich, H. C., 178; chloroform as ether solvent, 478; a study of anesthesia as a guide to the localization of lesions in the lower spinal cord and cauda equina, Starr, M. A., 626.
- Antony.** On the mechanism of the mammalian limb, Allen, H. A., 233; the reform of German anatomical nomenclature, Krause, W., 481; recent progress in anatomy, Dwight, T., 624.
- Animal.** On the mechanism of the mammalian limb, Allen, H. A.; tuberculosis in Jersey cattle; tuberculin as a diagnostic agent, 321.
- Ankle.** The management of compound dislocation of the ankle joint, Sennier, C. L., 324, 346; two cases of compound fracture and dislocation of the ankle-joint, 335, 346.
- Antiseptic.** Instestinal antiseptic, Ernst, H. G., 157, 171; Lister on antiseptics, 378.
- Appendicitis.** Two cases of appendicitis with abscess successfully treated by rectal puncture, Richardson, M. H., 261, 368; appendicitis, McMurtry, C., 401.
- Armstrong, H. E.** Suggestions for the regulation of dairy farms, 330.
- Army.** Report of the surgeon-general of the army for the year ending June 30, 1891, 20; the medical department of the army, 73; the appropriation for the library of the surgeon-general's office suggested, 20; the wounded of the World War battlefield, with remarks on wounds produced by large and small calibre bullets, Ewing, C. B., 463; first action of wounded soldiers, 660.
- Arsenic.** Chronic arsenic poisoning, Selmi, 201; inexpert examinations for arsenic, Folson, C. F., 227.
- Aspiration.** Intestinal aspiration, Bensel, W., 377.
- Atavism.** Infantile atavism, Robinson, L., 73.
- Ayer, J. H.** The third year of the influenza epidemic, 543, 553.
- Ayer, S. H.** A case of empyema with recurrence after apparent recovery, 547, 554.
- Bacillus.** Influenza, 19; bacillus of influenza, 101; the bacillus of influenza, Canon, 153; the public health in Massachusetts, typhoid fever and the typhoid bacillus, 223; passage of tubercle bacillus from the mother to the fetus, Birch-Hirschfeld and Schmal, 430; the bacillus of measles, Canon and Pielicke, 453; the bacillus of influenza, Pfeiffer and Beck, 645.
- Bacteriology.** Recent results of bacteriological results to prophylaxis and therapeutics, Edes, R. T., 628.
- Bacteriology.** Some of the recent advances in bacteriology, Ernst, H. C., 541; the bacillus of eclampsia, Gerdes, 562; practical results of bacteriological research, Sternberg, G. M., 669; the treatment of experimental tuberculosis by Koch's tuberculin, Hunter's modifications and other products of the tubercle bacillus, Trudeau, E. L., 610.
- Baldwin, Mrs. H. R.** Extraordinary mutilations from a railway accident, 320.
- Ball, A. B.** Dysentery; symptoms, complications and treatment, 221.
- Banana flour.** 227.
- Bardelbeben.** The new rifle projectiles, 286.
- Barney, C. N.** The cause of sea sickness, 301.
- Barry, J. S.** Some common causes of circumferential, 620.
- Barke.** Etiology of acute circumferential edema, 620.
- Bensel, W.** Aspiration from the patient's standpoint, 377.
- Bermann, E. von.** The Langenbeckhaus at Berlin, 129.
- Beri-beri.** Sinclair, A. W., 161.
- Bibliography.** Abbott, A. C., principles of bacteriology, a practical treatise for students and physicians, 206; Agnew, W. P., diagnosis and treatment of hemorrhoids and other non-malignant rectal diseases, 642; American Medical Association, addressess, papers and discussions in the Section of State Medicine, 145; Army, Report of the Surgeon-General of the Army for the year ending June 30, 1891, 20; Barr, J., the treatment of thyroid fever and reports of fifty-five consecutive cases with only one death, 206; Bartholow, K., a manual of hypodermic medication; the treatment of disease by the hypodermic or subcutaneous method, 425; Bonning, H. C., a treatise on practical anatomy for students of medicine, 178; Braine, C. H., Clinical Ophthalmology, 190; Braine report, 346; Boston Lyng-in-Hospital, fifty-nine year, 429; Bramwell, B., atlas of clinical medicine, 370, 557; Burdett, H. C., hospitals and asylums of the world: their origin, history, construction, administration, management and legislation, 18; Buzzard, T., on the relation of the heart and lungs to the circulation of the blood, 666; Cannmann, D. M., the physical diagnosis of the disease of the heart and lungs and throat and thoracic aneurism, 236; Chauveau, A., the comparative anatomy of the domesticated animals, 41; Clark, J. E., physical diagnosis and practical urinalysis, 396; Collier, R. Jr., the comparative anatomy of the domesticated animals, 149; Davis, N. S., Jr., consumption, how to prevent it and how to live with it, 21; Denmark: its medical organization, hygiene and demography, 236; Dunham, W. R., higher medical culture: medical science based on the four vital properties and laws of organic forces, 666; Eason, M. C., the state of pulmonary therapy, 172; Fox, W. H., creation on disease of the lungs and pleura, 612; Fullerton, A., nursing in abdominal surgery and diseases of women, 371; Gibson, G. A., and Russell, W., physical diagnosis, a guide to methods of clinical investigation, 173; Hamilton, F. H., a practical treatise on the diseases of the eye, 261; Hart, J. B., lectures on tumors from a clinical standpoint, 221; Hard, H. A., system of practical therapeutics, 261; Harvard University, annual reports of the President and Treasurer of Harvard College, 1890-91, 150; Huideker, R. S., age of the domestic animals, being a complete treatise on the dentition of the horse, ox, sheep, hog and donkey, with tables of ages of determining the ages of these animals, 123; Hard, E. P., sleep, insomnia and hypoxia, 456; Jamieson, W. A., diseases of the skin, 666; Johnston, A., Botany: a correct manual for students of medicine and science, 271; Kelsey, C. B., structure of the rectum: a study of one hundred and thirty-eight rectal specimens, 22; Kharatani, A. W., nose and its therapeutics, 371; McBride, P., diseases of the throat, nose and ear; a clinical manual for students and practitioners, 566; Maryland, Ninth Biennial report of the State Board of Health, 371; Massachusetts Board of Lunacy and Charity, thirteenth annual report, 347; Massachusetts General Hospital, Annual report, 1890-91; Massachusetts, Vital statistics for the year 1890, 374; Maya, T. J., pulmonary consumption a nervous disease, 371; Millard, H. B., a treatise on Bright's disease of the kidneys, 372; Moullin, C. W. M., surgery, a practical treatise with special reference to treatment, 221; Murdoch, C. B., cases of intestinal obstruction, 587; New York County visiting committee of the State Charities Aid Association, report, 43; Oster, W., the principles and practice of medicine, 399; Parker, E. A., a manual of practical hygiene, 345; Politzer, G., a manual of practical medicine, a synopsis of the human body, 337; Potter, O. L., handbook of materia medica, pharmacy and therapeutics, 477; Pozzi, S., treatise on gynecological medicine and surgery, 245; a system of gynecology, 615; Pozzi, S., treatise on gynecology, medical and surgical, 615; Recalino, P. C., the Mediterranean shores of America, Southern California: climatic, medical and meteorological conditions, 375; Robinson, F. B., practical intestinal surgery, 296; Rohr, G. H., a practical manual of diseases of the skin, 666; Roosa, D. B. St. J., treatise on diseases of the ear, 320; Senn, N., surgical bacteriology, 221, principles of

INDEX TO VOLUME CXXVI.

- ciples of surgery, 372; Sexton, S., and Duane, A., deafness and discharge from the ear, 387; Sheild, A. M., surgical anatomy for students, 296; Simon, W., manual of chemistry, 198; Stewart, D. D., and Lawrence, E. S., essentials of medical elect city, 425; Strahan, J., the diagnosis and treatment of extra-uterine pregnancy, 41; Sutton, J. B., surgical diseases of the ovaries and Fallopian tubes, including tubal pregnancy, 372; Tebb, W., leprosy and vaccination, 271; Thin, G., leprosy, 271; Thomas, T. G., a practical treatise on the diseases of women, 41; Thorne, R. T., diphteritis, its natural history and prevention, 221; Vaughan, G. C., and Nutt, F., the influence of leprosy and leprosy bacilli on the chemistry in the causation of disease, 232; Visiting-list for 1892 (Lea Brothers), 41; Vierordt, O., a clinical text-book of medical diagnosis for physicians and students based on the most recent methods of examination, 98; Walker, A. D., an introduction to human pathology, 172; Walker, J. H., the most valuable forms of early and physicians' vade-mecum, 945; Wood, C. A., lesions in the diagnosis and treatment of eye diseases, 345; Wood, H. C., therapeutics, its principles and practice, 425; Zeitschrift für orthopädische Chirurgie, 98.
- Biology.** Agnew, D. H., 304, 325, 677; Aitken, W., 672; Ayres, H., 24; Ayres, S., 203; Babcock, M. N., 540; Bartlett, E., 648; Berry, E. S., 48; Birdsell, W. H., 620; Bowditch, H. L., 67, 76, 226, 402; Bowman, W., 540; Brown, B., 23, 73; Brown, G., 481; Brueck, E. W., 48; Barnham, C., 201; Carpenter, A., 132; Clark, C. F., 24; Clark, S., 432; Conant, W. E., 228; Cross, C., 320; Cram, C. S., 31; Cushing, H., 222; DeChambeau, H., 291; Delaverrière, C. E., 322; Donlin, E., 620; Embree, J., 304, 510; Earle, F., 512; Elder, L. W., 512; Embree, J. R., 328; Federici, C., 620; Fiske, W. B., 481; Forman, H. E., 648; Gross, R. G., 401; Henn, H. W., 48; Hill, J. W., 76; Hillier, J. W., 201; Hinsdale, J. C., 380; Hobart, G., 450; Holden, W. S., 341; Husse, R. G., 597; Jarrett, C. S., 62; Jeffries, J. A., 328, 338; Jenkins, A. D.; Jones, C. M., 164, 180, 155; Kemp, C. P., 204; Kimball, J. E., 592; Long, W. H., 48; Luces, H. H., 132; Lummitz, A., 228; Lyman, G. H., 291; 313, 455; McIntrye, H. G., 328; Mackenzie, M., 201; Montard-Martin, O., 201; Morris, J. W., 48; Muller, H. K., 484; Mayo, H. O., 21; Messenger, J., 540; Metcalf, J. G., 76; Meynert, T., 620; Montard-Martin, E., 104; Montgomery, G., 364; Moore, J. G., 481; Moore, S. L., 200; Page, G. E., 132; Parker, E., 380; Paquet, A. H., 204; Peletton, C. W., 648; Pengra, C. P., 122; Porter, L. H., 156; Rehm, J. W., 201; Ross, G. H., 364; Rutherford, A. D., 201; Sauer, C. G., 132; Shove, H. W., 132; Skinner, D. N., 648; Smith, H., 132; Sprague, R., 672; Sproat, H. H., 361; Stahl, A. T., 301; Steiner, H. W., 201; Stillie, A., 450; Stillman, C., 484; Stillman, H. W., 105; Stoer, H. H., 29; 313; Sweeney, J., 228; Whitney, E., 484; Willard, H., 156; Wood, J., 48.
- "**Chloride of gold cure**" denounced by the Hampden District Medical Society, 453.
- Billary Infection.** Recent researches on billary infection, 373, 397.
- Billing, J. S.** The objective plane and needs of the laboratory of hypothyroidism, 395.
- Birch-Hirschfeld and Schmid.** Passage of tubercle bacillus from the mother to the fetus, 430.
- Birds as surgeons.** Fabio, 261.
- Birkett, J. G.** Gymnastic classes from Boston City Hospital, 38.
- Blakes, J. G.** and Prince, M. A case of functional monoparesis in a man, due to transmittion, recovery, 12.
- Blood.** The specific gravity of the blood, 246; origin of the red corpuscles, Mix, C. L., 255, 283; condition of the blood in certain mental states, Webber, S. G., 281.
- Bolton, T. L.** The growth of memory in school children, 646.
- Bomb-throwing and responsibility.** 71.
- Bone.** The removal of necrotic and carious bone with hydrochloric acid and gas, Morris, R. T., 123.
- Boston, J. A.** Spurious screening, 144.
- Boston.** The sanitary condition of Boston, a statistical paper, McCollum, J. H., 49, 64.
- Boston Lying-in Hospital.** Fifty-sixth year, 429.
- Bowditch, H. L.** 67, 402.
- Bowen, J. T.** Recent establishment of sanitariums for pulmonary diseases in the vicinity of our great cities, 190, 197.
- Bowen, J. T.** Recent progress in dermatology, 263, 288.
- Brackett, E. G.** Reflex in hip disease, 305, 320.
- Bradford, E. H.** Three cases of the separation of the epiphysis at the end of the femur; a case of hyperthyroidism in a child, 556.
- BRAIN.** The present status of cerebral surgery, Gray, I. C., 124.
- Brannan, S. W.** The diagnosis of empyema, 395.
- Breast.** A case of diffuse fibroma with a tendency to intracranial growth of both breasts, operation on each with an interval of three weeks, resection of one, 265.
- Brown, E.** Positive and negative correlation, 658.
- Brown, M. L.** A new, safe and sure method to expedite difficult cases of labor, 112, 278.
- Bryant, J. D.** The use of iodofom in the local treatment of struma, 201.
- Buckingham, E. M.** Some uses of the stomach-tube, 28, 36.
- Bulkley, L. D.** The non-contagiousness of leprosy, 22.
- Bullard, W. N.** Spastic paraparesis, 307, 319.
- Burrage, W. L.** Three cases of pus in the female pelvis, abdominal nodules, 163; the electrical treatment of pelvic inflammation, 600, 614.
- Burrell, H. L.** What is a felon? 108, 120; the management of gangrenous hernia, 200, 214; is it expedient to have a physical examination of men before enlisting them in State troops? 469, 511.
- Burnett, H. L.** and Cushing, H. W. Recent progress in surgery, 443, 528, 626.
- Cabot, A. T.** Two cases of cholecystotomy, 418, 423; papilloma removed from the bladder, 477; the treatment of pelvic abscess, 493.
- Callie, A.** Experiments as to the value of nascent ozone in certain diseases of children, with demonstration of an efficient generator, 476.
- Cambridge.** Season and disease-prevalence in Cambridge, 1888-1889 inclusive, Farnham, E., 439.
- Canon.** The bacillus of influenza, 153.
- Canon and Phlebotomy.** The bacillus of measles, 453.
- Cardiac System.** The different forms of cardiac pain, Chew, S. C., 658; some non-valvular heart murmurs, Davis, N. S., Jr., 668; the importance of position in examination for disease of the heart, Campbell, O. H., 661.
- Carmichael, W. H.** Conditions demanding excision of the globe of the eye, 607.
- Campbell, O. B.** The importance of position in examination for disease of the heart, 661.
- Carey, C.** The production of tubular breathing in consolidation and emphysema of the lungs, 628.
- Carrier, E. C.** Myxomas with insanity treated by injection with extract of thyroid gland, 181.
- Castro.** Capital punishment as a punishment for crime, Hammond, W. A., 331.
- Chadbourne, A. P.** Dr. Oscar Liebreich's improved method and instruments for the examination of the skin, especially in lupus, 286.
- Chadwick, J. R.** The pathology, diagnosis and treatment of pelvic inflammations, 495.
- Chapin, H. D.** Quarantine and disinfection in limited apartments, 269.
- Chenevay, E.** A new and safe way of expediting difficult cases of labor, 265.
- Cherry, F. E.** Ocular headaches, 10; purulent ophthalmic neovascularization, 20.
- Chew, S. C.** The different forms of cardiac pain, 658.
- Chicago.** Typhoid fever in Chicago, 153.
- Childs, W. B.** Recent progress in diseases of children, Rotch, T. M., 33; infantile asthenia, Robinson, L., 73; the work-variation of a child's hour of study, 322; purulent ophthalmic neovascularization as a cause of blindness, Cherry, F. E., 266; empyema in children, 20; the primary importance of the tonsil in the causation of rheumatism with effusion, Knobell, H., 394; annual meeting of the American Pediatric Society, 473; experiments as to the value of nascent ozone in certain forms of diseases of children, with demonstration of an efficient generator, Callie, A., 473; manifestations of a grippe in children, 20; 473; epizootic of cholera in an orphan asylum for girls during the year 1891, Putnam, C. F., 474; two tracheal and bronchial casts, Huber, F., 475; typhoid fever in children under two years, Northrup, W. F., 506; typhoid fever in children, Earle, C. W., 501; typhoid fever in infancy, Christopher, W., 502; typhoid fever in congenital cretinism, Townsend, C. W., 502; syphilis and syphilitic broncho-steatitis in children, Soper, A., 502; the relation of rheumatism and chorea, Townsend, C. W., 503; the value of milk laboratories for the advancement of our knowledge of artificial feeding, Rotch, T. M., 505; a case of hysterectomy in a child, Bradford, E. H., 536; the growth of memory in school children, 20; 474.
- Chittenden, H. R.** and Fairley, J. W.
- Case of alleged naphtha poisoning in a rubber factory, with an inquiry into the effects of the inhalation of naphtha vapor,** 621, 640.
- Chloroform.** *ra.* either again 478; the use of chloroform, Cottrell, B. C., 50; the recent improvement of chloroform syncope by massage of the heart, Marx, 501.
- Chorea.** The relation of rheumatism and chorea, Townsend, C. W., 501; a study of the seasonal relations of chorea and rheumatism for a period of fifteen years (1876-1890), Lewis, M. J., 636.
- Christopher, W. S.** Typhoid fever in infancy, 501.
- Christopher, W. S.** Retained feces, 668.
- Chronic diseases.** Provision for patients with chronic diseases in the city of Boston, Knapp, P. C., 381, 393.
- Church, A.** The vertigo of arterio-sclerosis, 636.
- Circulatory System.** Fat embolism, Whitney, W. F., 159, 170; the effect of the administration of ether on the blood vessels, Mix, C. A., 225, 233; condition of the blood in certain mental states, Webber, S. G., 281; subcutaneous blood injection and infusion, 522; mid-systolic and late systolic mitral murmur, Griffith, J. F. C., 620; the vertigo of arterio-sclerosis, Church, A., 630.

Degarmo, W. B. A few points on the management of strangulated hernia, 665.
Derry, H. Recent added facilities for the examination of the eye, 574.
Dermatol. Bacteriological and clinical investigations into the action of dermatol, Stone, A. K., 422.
Detroit. Letter from Detroit: American Medical Association meeting, 585.
Diabetes. A case of glycosuria caused by a lesion probably situated near the fourth ventricle, Stone, A. K., 392, 393; the liver in diabetes, 506; recent investigations of the etiology of diabetes mellitus, Kramer, S. P., 639.
Digges, W. The causation and treatment of chronic diarrhoea, Valanz, W. W., 241.
Digestive System. *Bacillus coli communis*, 19; some uses of the stomach-tube, Buckingham, E. M., 28; a case of biliary calculus, cholecystotomy, duodenal fistula, recovery, Adams, J. F. A., 49; a case of intestinal obstruction due to a palpable mass, 20; the greater part of the contents of doubtful origin, external epipharynx and attempts at distillation, death, Richardson, M. H., 58; cyst of the pancreas treated by laparotomy, drainage, recovery, Richardson, M. H., and Mumford, J. G., 88, 92; abdominal section in a case of cyst of the liver, Rogers, J. A., 122; intestinal obstruction, Evans, H., 187, 188; the treatment of strangulated hernia, Bell, George W., 207, 213; the management of gangrenous hernia, Bell, H. L., 209, 214; a case of intestinal resection and suture for artificial anus following gangrenous hernia, Richardson, M. H., 211, 212; the causation and treatment of chronic diarrhoea, Valanz, W. W., 241; a case of appendicitis, 240; a case of intestinal obstruction treated by rectal puncture, 240, 248; intestinal dyspepsia, 272; a case of impetigo rectum, Conant, W. M., 297, 294; three recent cases of oesophagotomy, Gay, G. W., 322, 342; recurrent tumor in the throat, Richardson, M. H., 320; tumor of esophagus causing intussusception, Richardson, M. H., 320; a case of appendicitis treated by laparotomy upon an examination of the peritoneum, Van Pelt, G. W., 388, 391; a case of glycosuria caused by a lesion probably situated near the fourth ventricle, Stone, A. K., 392, 393; appendicitis, McBryne, C., 401; on resection of the liver, especially for hepatic tumors, Keen, W. W., 405, 423; gall-bladder surgery, 410; removal of a tumor, secondary to a pistol wound of the liver, with a report of a case, Gage, H., 416; two cases of cholecystotomy, Cabot, A. T., 416, 423; retention cyst of the gall-bladder, Mizter, S. J., 420, 424; case of cholecystotomy, Gay, G. W., 421, 423; two cases of abscess of the liver, Irish, J. C.; large and multiple abscesses of the liver successfully treated by laparotomy and drainage, Richardson, M. H., 422, 423; treatment of tonsillar hyperplasia, Wright, J., 471; micro-organism in the saliva, Samarelli, 510; a remarkable anæmia, 516; intestinal evacuation in operations for obstruction, Smith, G.; another unusual anæmia, 563; dysentery; etiology and pathology, Conant, W. M., 563; a case of intestinal obstruction, treatment, Ball, A. H., 634; treatment of acute dysentery by antiseptic colons and rectal irrigation, Johnston, W. W., 635; hepatic abscess, Dabney, 635; effect of Mites on gastric movements, Terry, 636; a case of recurrent appendicitis, operation, recovery, Munro, J. C., 638; microcosm of the intestine, reported by a German physician, Stärkert, C., 657; retained feces, Christopher, W. D., 660; catarrhal gastritis, Mayer, H. N., 660.
Diphtheria. Feeding in diphtheria, forced feeding, Holt, L. E., 270; constitutional changes, Holt, L. E., 270; the disease, 269; presented in the tox-albumen of diphtheria, Welsh, 270; recent investigations relating to the prevention of diphtheria and scarlet fever, Smith, J. L., 568; forms of diphtheria which simulate simple angina, Koplik, H., 475.
Directory. A medical directory hubung, 539; a proposal of the Boston City Hospital, 539.
Disinfection of the hands, Kelly, H. A., 154.
Dislocation. An unique dislocation of the foot and of the astragalus, H. A., 195.
Draper, F. W. Recent progress in legal medicine, 142; the medical profession and the commonwealth, 565, 566.
Drexel Institute, 45.
Drugs. Absorption of drugs by the skin, 199; bill for pure food and drug, Paddock, 276.
Drunkenness and crime, James, H., 321.
Dysentry. Typhoid, staphylococcal pathology, Connelman, W. L., 316; typhoid exanthem, complications and treatment, Ball, A. H., 634; treatment of acute dysentery by antiseptic colon and rectal irrigation, Johnston, W. W., 635.
Dudley, J. W. Observations on albuminuria in scurifaria, 138, 160.
Dwight, T. Recent progress in anatomy, 624.
Dyspepsia. Case of dyspepsia and treatment based upon an examination of the gastric juice, Van Pelt, G. W., 385, 391; the place of dyspepsia in general nosology, 676.
Ears. The removal of lead from the ear, Sheild, 516; operative treatment for the relief of chronic suppurative affections of the middle ear, results in 100 cases, Jack, F. L., 548, 554.
Earle, C. W. Manifestation of the grippe in children, 473; typhoid fever in children, 501.
Edes, R. T. The relations of bacterio-chemical results to prophylaxis and therapeutics, 635.
Editorial. The *Bacillus coli communis*, 19; report of the surgeon-general of that army for the year ending June 30, 1891, 20; the Association of Military Surgeons of the National Guard, 21; the present influenza epidemic, 21; the annual report of the New York County Visiting Committee of the State Charities Aid Association, 43; the Drewry Industrial Home, Boston, Bradford, M. D., 60; the treatment of influenza, 50; bomb-throwing, responsibility, 71; the nervous and mental phenomena and sequænae of influenza, 95; restricting the distribution of scarlet fever, 100; the bacillus of influenza, 101; typhoid fever in Chicago, 126; annual reports of the president and treasurer of Harvard College, 1890-91, 156; the quarantining of influenza, 151; vaccination statistics, 151; typhus fever in New York, 173; suicide in the European armies, 174; hygienic legislation, 175; absorption of drugs by the skin, 199; typhus fever in New York, annual appropriations for hospitals in Boston other than the City Hospital, 200; the plague in Massachusetts, typhoid fever and the typhoid bacillus, 222; Hertwig's theory of immunity, 223; specific gravity of the blood, 236; etiology and nature of typhus fever, 247; the appropriation for the library of the Army and Navy, 250; the treatment of typhoid fever, 248; intestinal dyspepsia, 272; treatment of neurasthenia by trichloroform (hypnotic injection) of nervous substance, 273; word-blindness, 274; evolution and heredity, 299; tuberculosis in Jersey cattle, tuberculin as a diagnostic agent, 321; neuralgic and neuralgic affections, 321; the voice-variation of a child's hair of study, 322; the obligations of medical practice, 327, and of physicians to their patients, the thirteenth annual report of the Massachusetts Board of Licensure and Charity, 347; the annual report of the Boston City Board of Health, 348; recent researches onillary infections, 373, 397; the vital statistics of Massachusetts for the year 1890, 374; the treatment of influenza, 375; cases of death from influenza for the years 1880 and 1881, 394; the regulation of medical expert testimony, 398; the report of the medical officer of the Local Government Board, 426; the Hospital Saturday and Sunday Association, 426; surgery of the liver, 427; presentation of portraits of Dr. Oliver Wendell Holmes, Dr. Allyn, Dr. Allen, Dr. C. L. Shattuck, Dr. Phillips, Philadelphia, 428; chloroform vs. ether once again, 478; the vegetarian's heart, 478; the meat-eater's heart, 478; the Allyn murder trial, 484; the liver in diabetes, 506; sex in education, 567; seventy-eighth annual report of the Massachusetts General Hospital and McLean Asylum, 568; an additional report on the practical organic disease, 553; treatment of acute rheumatism in the Passaic mills, 553; first action of wounded soldiers, 560; electric lighting in its relation to public health, 560; too long vacations, 567; the exhibit at the annual meeting of the Massachusetts Medical Society, the 1891 course of instruction, 568; the four years' course at the Harvard medical school, 616; malarial infections, 612; the place of dyspepsia in general nosology, 676.
Education. The four years' course at the Harvard medical school, Flitz, R. H., 599; the four years' course at the Harvard medical school, 600.
Electricity. Execution by electricity, Van Gieson, L., 201; on the value of electricity in minor gynaecology, Reynolds, E. P., 214; electric lighting in its relation to public health, 560; the electrical treatment of pelvic inflammation, Barrage, W. L., 600, 614.
Emotions. The influence of emotions in the production of organic disease, 535.
Empyema. In childhood, is it ever primary? its relations to pneumonia and to pleurisy with effusion, Koplik, H., 34; the diagnosis of empyema, Braman, S. W., 395; operation for empyema, Ripley, J. H., 395.
Endometritis. Thinness of uterine walls simulating extra-uterine pregnancy, with report of two cases, 122.
Epilepsy. On the relation of epilepsy to injury of the head, Pannam, J. J. I., 13; two cases of trephining for traumatic epilepsy, Knapp, P. C., and Post, A., 5, 13; a sure cure for epilepsy, 179; the surgical treatment of epilepsy, Price, J., 315; malarial epilepsy, Hill, E. W., 631.
Kernst, H. C. Intestinal antispasmodic, 157, 171; some of the recent advances in bacteriology, 541.
Ewing, C. B. The wounded of the Wounded Knee battlefield, with remarks on wounds produced by large and small calibre bullets, 98.
Erysipelas. The contagiousness of erysipelas, Reed, W., 237.
Ether. Chloroform vs. ether again, 378.
Everett, W. The American physician, 598.
Evolution. Evolution in physiology, 535.
Expert. The regulation of medical expert testimony, 398.
Extra-uterine pregnancy. Tubal pregnancy, a case, Washburn, G. H., 30, 31; a case of probable tubal pregnancy, Reynolds, E., 31; a case of tubal pregnancy, Harrington, F. B., 31, 37; extramural pregnancy, tubal, ectopic, recovery, Johnson, F. W., 60; thinness of the uterine walls simulating extra-uterine pregnancy, Engelman, G. J., 122.
Eye. Ocular dermato-syphilis, Cheney, F. E., 10; two cases of corneal wound with prolapse of iris, Green, J. A., 111; the quadrilateral of the right eye, and motor hemiplegia, Parsons, J. J., 113; the Mongolian eye, Kimoto, 226; astigmatism as an element of refraction, and its objective study by the ophthalmometer of Javal and Schlötz (model of 1890), Swayze, 222; family position of the head and neck due to the eyes, and corrected by head and neck exercises, 338; the condition of the eye in ophthalmia neonatorum as a cause of blindness, Cheney, F. E., 362, 366; recent added facilities for the examination of the eye, Derby, H., 574; conditions demanding enucleation of the globe of the eye, Carmalt, W. H., 607; toxic retro-bulbar neuritis, Coggins, D., 647.
Fabin. Birth pangs, 261.
Fairbank, E. Season and disease-prevalence in Cambridge, 1880-81 inclusive, 438.
Fat embolism, Whitney, W. F., 159, 178.
Fat, G. E. Additional evidence of the value of forced respiration, Fenner, T. C., 10; a case of fat embolism, Burrell, H. L., 108, 120.
Femur. Three cases of the separation of the epiphysis at the head of the femur, Bradford, E. H., 212.
Fitz, R. H. The pathology of pelvic inflammation, 491; the four years' course at the Harvard medical school, 599.
Fletcher, C. W. A possible source of error in using the fever thermometer, 303.
Folsom, C. F. Inexpert examinations for arsenic, 227.
Food. A bacteriological examination of the Boston milk-supply, Sedgwick, W. H.; the Boston milk-supply, J. L., Jr., 25; feeding in diphtheria, forced feeding, Holt, L. E., 270; bill for pure food and drugs, Paddock, 276; banana flour, 277.
Fractures. The treatment of uncomlicated fractures of the lower end of the humerus, Roberts, J. B., 588.
Gage, H. Secondary laparotomy for pistol wound of the liver, with a report of a case, 476.
Gardiner, W. T. Dr. Henry Ingessell Bowditch, 462.

INDEX TO VOLUME CXXVI.

- Gaston, J. M.** Surgery of the gall-bladder and ducts, 663.
Gay, G. W. The treatment of gangrenous hernia, 207, 213; three recent cases of esophagotomy, 322, 342; cases of cholecystotomy, 324, 423; a collection of calculi recently removed from a bladder by lithotripsy, 531.
- Generative System.** Gynecological cases from the Boston City Hospital, Blake, J. G., 38; two cases of ruptured uterus treated expectantly, Reynolds, E., 80, 90; rupture of the uterus, with the report of a case, Haven, C., 83, 90; removal of a large uterine fibroid and abdominal hysterectomy, Cushing, E. W., 85, 92, 145; complications in pelvic surgery, and how to deal with them, Price, J., 95; ovarian cysts, with the report of a case of ovariotomy in a young girl, Kelloock, C., 95; a medical legal aspect to pelvic inflammation, Potters, C. W., 96; the growth of the uterus, with the report of the increase in size, Haven, J. T., 97; the surgical treatment of anterior displacements of the uterus, Reed, C. A., 97; a case of laparotomy for ovarian disease, Kingman, R. A., 140, 145; a case of papilloma of the ovary and Fallopian tube, Green, C. M., 142, 148; glandular cystoma, Harrington, C. B., 149; three cases of primary ovarian disease, Bunting, W. L., 163; fibroid cyst, Porter, C. B., 172; two ovariotomies, Gifford, B. D., 237; the relief of spasticity by dilatation and drainage of the uterus, Strong, C. P., 258, 266; cases of laparotomy presenting features of unusual interest, Strong, C. P., 359, 367; recent progress in gynecology, Kingman, R. A., 367; a case of ovarian tumor, with a report on the pathology, Reynolds, E., 381; the pathology of pelvic inflammation, Fitz, R. H., 491; cyst of the broad ligament, Strong, C. P., 495; the treatment of pelvic abscess, Cabot, A. T., 493; the pathology, diagnosis and treatment of pelvic inflammation, Chadwick, J. H., 495; a case of uterine fibroids, with report of a case of primary and secondary operations, Reynolds, E., 522, 531; a case of hysterectomy in a child, Bradford, E. H., 532; a uterus in a seroton, Bokslé, 563; case of ovariotomy, Davis, G. W., 571; fibroid tumors of the uterus, Homans, J., 585; the electrical treatment of pelvic disease, Barrage, W. L., 600, 614; report of a case of persistent spasticity, Van Peet, G., 603, 614.
- Gerdes.** The bacillus of ectoplasia, 562.
- Gerri Maniac.** 327.
- Gifford, B. D.** Two ovariotomies, 237.
- Goggans, J. A.** Abdominal section in a case of cyst of the mesentery, 123.
- Goitre.** The operative treatment of goitre, Warren, J. C., 433, 447.
- Gold.** The bichloride of gold fraud, Abbott, S. W., 75; "bichloride of gold cure" denounced by the Hampden District Medical Society, 455.
- Goldsmith, J. E.** Charcot's disease of both hips, 423; forcible straightening for permanent flexion of the knee, 423.
- Graham, D.** The treatment of chronic sprains of the finger-joints, 102.
- Graham, J. T.** The treatment of the criminal insane, 276.
- Gray, L. C.** Unfavorable secondary effects of sulphur, 113.
- Gray, L. C.** The present status of cerebral surgery, 124.
- Green, C. M.** Report on progress in obstetrics, 62; a case of papilloma of the ovary and fallopian tube, 112, 118; remarks at meeting of section in obstetrics and gynecology, Suffolk District Medical Society, 146; the care of women in pregnancy, 186, 194; placenta praevia complicated with uterine and impending ectoplasia, 531, 557.
- Greenwood, A.** Two cases of corneal wound with prolapse of iris, 111.
- Griffith, J. P. C.** Mid-systolic and late systolic mitral murmurs, 628.
- Gronvald, C.** Leprosy in Minnesota, 538.
- Gunshot Wounds.** The wounded of the Wounded Knee battlefield, with remarks on wounds produced by large and small calibre bullets, Brinkley, C. B., 10; first aid of wounded soldiers, 560; the new rifle practice, Bardeleben, 596.
- Haggard, W. W.** The part the shoulders play in producing laceration of the perineum with suggestions for its prevention, 97.
- Hann, J. R.** An unique dislocation of the foot and of the astragalus, 495.
- Harmmond, W. A.** Castration as a punishment for crime, 351.
- Hands.** Disinfection of the hands, Kelly, H. A., 154.
- Hare, H. A.** Collective investigation in regard to the value of quinine in malarial haematura or malarial haemoglobinuria, 656.
- Harrington, E. A.** A case of tubal pregnancy, 31, 37; glandular cysts, 142.
- Hartwell, B. H.** So-called spontaneous combustion, 135.
- Harvard University.** Annual reports of the president and treasurer of Harvard College, 1890-91, 159; the four years' course at the Harvard medical school, Fitz, R. H., 399; the four years' course at the Harvard law school, 400.
- Haven, G.** Rupture of the uterus, with the report of a case, 83, 96; a report of three cases of craniotomy, 269, 267.
- Headaches.** Ocular headaches, Cheney, F. E., 10.
- Henry, J. C.** Malaria and pyrexia, 228.
- Hernia.** The treatment of gangrenous hernia, Gay, G. W., 207, 213; the management of gangrenous hernia, Burrell, H. L., 200, 214; a case of intestinal resection and suture for artificiai anus following gangrenous hernia, Richardson, M. H., 211, 213; femoral and ventral hernia in woman, Coley, W. B., 326; hernia operable and inoperable, 327; a few points on the management of strangulated hernia, Degarmo, W. B., 607; the management of gangrenous hernia, Randolph, J., 605; hernia, Marey, H. O., 605.
- Hertwig's theory of immunity.** 223.
- Henrotin, F.** International periodical congress of gynecology and obstetrics, 13.
- Hill, E. W.** Malarial epilepsy, 631.
- Hip.** Congenital dislocation of the hip, Phelps, A. M., 77, 93; reflexes in hip disease, Brackett, E. G., 305, 320; Charcot's disease of both hip-joints, Goldthwaite, J. E., 423.
- Hilliard, J. C.** A modified form of continued fever following the epidemic grippe, 639.
- Holmes, E. L.** Preparation of the study of medicine, 670.
- Holt, L. E.** Feeding in diphtheria; forced feeding, 270; a simple method for clinical examination of breast milk, 595.
- Homans, J.** Fibroid tumors of the uterus, 585.
- Hospitals.** Annual appropriations for hospitals in Boston other than the City Hospital, 200; hospital Saturday and Sunday association, 427.
- Hutchingsons.** Two tracheal and bronchial casts, 435.
- Hydrocephalus.** Discussion of disease, 600.
- Hydrophobia.** A case of hydrophobia, Pierre, G. C., 59; the cure of a case of hydrophobia, Murrl, 616.
- Hygiene, Health and Boards of Health.** The sanitary condition of Boston, a statistical paper, McNamee, J. A., 49, 50; vaccination in Boston, F. C., 13; the quarantining of infectious, 151; hygiene legislation, 175; the objects, plan and needs of the laboratory of hygiene, Billings, J. S., 181; address delivered at the opening of the laboratory of hygiene of the University of Pennsylvania, Lee, B., 184; the public health in Massachusetts; typhoid fever and cholera in Boston, 222; recent progress in public hygiene, Abbott, S. W., 311, 336; the report of the medical officer of the local government board, 426.
- Hypnotism.** Debate on the therapeutic value of hypnotism, 145.
- Incurables.** Path of incubators, 377.
- Infection.** Some data on infection incidental to professional life, White, J. C., 105, 116.
- Influenza.** The present influenza epidemic, 42; the treatment of influenza, 70; the nervous and mental phenomena and sequelae of influenza, 75; the treatment of influenza, Crampton, J. E., 139; the quarantining of influenza, 141; the bacillus of influenza, Cannon, 153; cutaneous eruptions in influenza, Mason, C. F., 162; two fatal cases of cerebral disease (one of confusional insanity, the other of doubtful nature) following grippe, Prince, M., 163; the recent epidemic of influenza, Bunnell, 262; a case of influenza at sea, Mac Gowen, D. G., 433; manifestations of influenza in children, Earle, C. W., 433; pneumonia in Boston during the recent epidemic of influenza, Shattuck, G. B., 518, 532; the third year of the influenza epidemic, Ayer, J. B., 541; 553; menzies, J. E. Link, 633; a modification of the vaccine for fever following the grippe, Hollister, J. H., 639; the bacillus of influenza, Pfeiffer and Beck, 645; a case of influenza with eruption, Robinson, S. G., 652.
- Insanity.** The treatment of the criminal insane, 276.
- Instruments and apparatus.** Some uses of the stomach tube, Bright, J. C., 10; the use of the rectal enema, 207; the rectal enema and cast for use in mouth and nose, Winter, J. E., 209; the water bag as a means of affecting the temperature of the body, Wood, H. G., 271; a possible source of error in using the fever thermometer, Fletcher, S. W., 303; Dr. Oscar Liebreich's improved method and instrument for examining the skin, especially in lupus, Chaudhury, A. P., 304; an improved method for taking venous pressures; experiments as to the value of nascent ozone in certain forms of diseases of children, with demonstration of an efficient generator, Callie, A., 473.
- Irish, J. C.** Two cases of abscess of the liver, 421.
- Irish, J. C., and Stone, A. K.** Abdominal and pelvic emergencies causing sudden death, 624.
- Italy.** Causes of death in Italy for the years 1889 and 1890, 308.
- Jack, E. E.** Faulty position of the head and neck due to the eyes, and corrected by traction of the eye muscles, 310, 329.
- Jackson, J. L.** External ear; treatment of chronic suppulsive affections of the middle ear; report of three cases, 545, 551.
- Jacobi, A.** A case of spinal blindness, 235; Constitutional treatment in diphtheria, 270; a note on peroxide of hydrogen, 593.
- Jacob, M. P.** Pachymeningitis and myelitis, 342.
- James, H.** Drunkenness and crime, 324.
- Jansen, W.** Medical notes from Japan, Stephenson, F. B., 15; sanitation in Japan, Stephenson, F. B., 131; letter from Japan, Stephenson, F. B., 202, 278.
- Jefferson Medical College.** New buildings for the Jefferson Medical College of Philadelphia, 230.
- Jones, F. W.** Extramaterne pregnancy, cesarean, recovery, 662; two cases of pregnancy and labor at term, following the Alexander-Adams operation, 363.

Original Articles.**ON THE RELATION OF EPILEPSY TO INJURY OF THE HEAD.¹**

BY JAMES J. PUTNAM, M.D.

AT the recent Congress in Washington the important subject of traumatic epilepsy from fracture of the skull was brought up by Dr. Agnew,² of Philadelphia, in the course of his paper on "The Surgery of the Brain." After speaking of the unsatisfactory results of operative treatment after the neurosis has once established itself, he expressed the opinion that the improper surgical treatment of the case at the time of the occurrence of the fracture is responsible for much of the subsequent mischief, and, went on to say: "Whenever, therefore, in my judgment, the profession can accept the doctrine that all depressed fractures of the cranium, however slight may be the depression, and entirely irrespective of pressure symptoms, are proper subjects for trephining, then will traumatic epilepsy largely disappear from the list of surgical diseases; indeed, I am sure that he who shall propose to tabulate, at the end of the next twenty-five years, the cases of epilepsy, will find, as compared with the present time, a meagre supply for his purpose. It is not improbable, indeed, in view of the greatly diminished risk from trephining, that the operation will be extended even to cases of simple fracture or fissure of the skull."

It will be fortunate, indeed, if this optimistic view turns out to be well founded. Since, however, it is of the highest importance for us to know, in detail, on just what principles we ought to proceed, when called to a case of fracture, and how much immunity from epilepsy or insanity we can promise our patient in return for his submitting, though free from symptoms, to trephining and perhaps to opening the dura, it seems worth while to re-examine the evidence as to the frequency and the causes of the unwelcome result and the possibility of avoiding them.

The adoption of this view assumes that the cause of the epilepsy is the irritation at the seat of principal injury, and especially the irritation due to displaced fragments of bone,³ and the failure of late operations for removal of the bone to effect a cure is considered as due to the epileptic habit having become established.

It is difficult to test the correctness of this explanation, but it is not an altogether satisfactory one. It is common enough to see cases where trephining, undertaken after a certain number of fits have occurred, do check their recurrence for several years, long enough, one would think, to break up the epileptic habit, if there were nothing else besides the irritation starting from the depressed bone to maintain it. But not only do the fits almost always recur in the end after trephining, but they usually recur when, besides the bone, portions of the cortex, which the symptoms indicated to be the centres of origin of the attacks, have been removed likewise, as Dr. Agnew himself points out.

Moreover, the recent excisions of motor areas which were apparently responsible for outbreaks of ordinary

¹ Read before the Boston Society for Medical Improvement, November 2, 1891.

² Published in the University Medical Magazine, Philadelphia, October, 1891.

³ Dr. Agnew (loc. cit.) speaks particularly of the irritation of the sensory nerves of the dura by depressed or broken bone, "an irritation propagated to the meninges, and, later on, to the cortex and brain-ganglia."

epilepsy of the localized type, also seem to be far less effective than was hoped. The attacks are usually arrested, sometimes for one or two years, or even longer, and in exceptional cases they may never return; but this is hardly more than seems occasionally, (though less often) to happen after other operations where neither cortex nor diseased bone are removed, so that, important as both trephining and cortical excision may be as a means of treatment, where we wish to gain a temporary respite, or to take every chance of cure, they must for the present count rather as excellent inhibitory measures, than as proving the nature or origin of the disease.

If Dr. Agnew's opinion, which represents that of many surgeons, cannot be sustained by evidence, and the patient's prospects are not improved by treatment of the local injury to anything like the degree indicated, it is eminently important that we should not let ourselves be turned aside by it from the search for other influences that may turn out to be equally important in the causation of epilepsy. If, on the other hand, that opinion can be sustained, and if trephining carries with it so little risk of inducing either immediate or subsequent mischief, then, I think, it should be seriously considered whether we ought not to trephine, also, in cases of healed fracture that come to us not too long after injury, but before epileptic symptoms have appeared.

There is, of course, no question as to the propriety of trephining, in many cases of fracture even without symptoms, on general surgical grounds. The indications for doing this have been clearly laid down by various writers, and among others by Wagner, in an excellent address published in 1886 as Nos. 271, 272, of Volkmann's *Klinische Vorträge*. The treatment there advised is based almost wholly on the importance of preventing or curing local infection, though with the secondary aim of getting rid of irritating fragments of bone. Simple depression is considered as dangerous, not as a cause of intracranial pressure, but only in that it is liable to interfere with the union of the broken bones and lead to suppuration by disturbing the circulation in the diploe, and he recommends that when the fracture is not compound a moderate depression should be left untreated. Linear fracture without symptoms, even when compound, is considered as calling for treatment only when hairs or other foreign substances are caught in the crack, and then he uses the chisel so far as is necessary for removing them.

Wagner recognizes at the same time that trephining is a relatively trifling operation.⁴ He urges it for localized meningitis, or to secure a more aseptic condition of the broken bone and underlying parts, as in perforating wounds, and even, in case of doubt, for exploring the condition of the tissues beneath the bone, especially when suppuration of the dura is suspected.

Although Wagner considers it important to remove broken fragments of the inner table when feasible, he calls attention to the fact that they generally heal smoothly if left alone, and this opinion gains some support from the fact that the osseous plates which so often form in the dura usually do no harm, though they are considered by some pathologists⁵ as of inflammatory origin.

⁴ Dr. Manley, of Brooklyn, demurs to the view that trephining after injury is so safe, and quotes cases to show the danger of hernia cerebri.

⁵ See Ziegler's Handbook of Pathological Anatomy.

Do we know with any approach to accuracy how much immunity from epilepsy is secured by early trephining,⁹ or in what class of cases immunity is secured at all?

The absolute evidence of the character necessary for answering these questions is small in amount. No systematic attempt has been made by any writer to compare, as regards the subsequent occurrence of epilepsy, any large series of cases in which the skin, bone and underlying parts were treated early by the best modern methods of surgery, with a similar number which were not so treated; and, on the other hand, there are plenty of individual cases on record where, under such treatment as was adopted, the parts healed satisfactorily and showed later no sign of disease, and yet epilepsy supervened.

Among the cases of fracture, especially of gun-shot fracture, occurring in our late war,¹⁰ this happened repeatedly, though of course the methods then followed were not as thorough as those in use to-day.

An analysis of these cases made for me by Mr. F. Coggeshall, shows that five per cent. of the patients trephined at the time of injury subsequently had epilepsy, and that thirty-two per cent. of all the patients who became epileptic later had been trephined at the time of injury.

It is not enough to point out that cases of epilepsy following properly treated fracture do not present themselves in our dispensaries and consulting-rooms, for the whole number of cases that would be admitted by the best surgeons as having been properly treated is extremely small, and the proportion of cases in which epilepsy occurs after fracture, treated or not treated, is also a small one, though the danger is apt to loom up prominently when we are first called to such a case.

Does the simple persistence of a depression in the bone, for example, without detached fragments or signs of inflammatory processes, at the end of a number of years, prove that the case was not properly treated at the outset? From the point of view of surgical treatment we should perhaps have to answer yes, but, in fact, it is doubtful whether the chances of epilepsy are really much increased by such a condition, except where the displacement prevents the bone from healing properly, as sometimes happens.¹¹

Not only is it common enough to see depressions in the skull without epilepsy, but it is difficult to see why epilepsy should result unless the depression is the cause or accompaniment of osteitis or meningitis, or changes in the nutrition of the brain, and that these results usually occur is not shown by the records of subsequent operations or post-mortems, or by the inspection of the specimens in our museums. Microscopic investigations might tell a different story, but at any rate there is no reason to think that the simple increase in intracranial pressure from a moderate depression causes symptoms of cerebral compression, except sometimes at the outset. If depression in itself is a cause of epilepsy it must be because, as Dr. Agnew suggests, it sets up an irritation of the dural nerves, and, in some way not known to us, possibly by way of neuritis, an impairment of the cerebral nutrition.

It must, I think, be admitted, with regret, that the view which looks for so much security in the treatment of the fractured and depressed bone is not based

⁹ This term is to be taken, of course, as covering all the measures used in exploring the injury of the bone and underlying parts.

¹⁰ Surgical History of the War of Rebellion.

¹¹ Compare Wagner (*loc. cit.*).

upon a sufficient recognition of the obscurity which still surrounds the origin of epilepsy, and of the variety of the possible causes liable to be set in action by severe injuries to the head, some of which are amenable to early treatment, while others are not.

The study of epilepsy as it occurred among the German troops in the late Franco-German war is full of interest in this connection.¹²

It is, in the first place, worthy of note, that by far the greater number of cases occurring in the German army and due to army life were of other than traumatic origin,¹³ because it reinforces the view that epilepsy is usually a general cerebral neurosis.

That it may arise from purely local cerebral disease seems unquestionable, especially when we consider that it may be excited in animals by localized faradization of the cortex. But in many of the traumatic cases, and especially where the outbreaks do not occur until years after the injury, influences are present affecting the nutrition of large areas of the brain, and these certainly constitute possible causes of the disease.

Of the sixty-three traumatic cases (omitting a large number of epileptiform vertigos, etc., and a few unclassified cases) forty-six followed injuries of the head, seventeen, injuries of the body and limbs.

Again, epilepsy occurred out of

8,985	injuries of the head	28 times = 0.31 %
11,091	" neck and trunk	5 " = 0.04 %
35,700	" arms	5 " = 0.015 %
35,670	" legs	7 " = 0.02 %

The greater number of the epilepsies from head injury appeared to be from sensitive scars of the scalp, combined with the effects — difficult to estimate — of cerebral contusion and concussion; but that these latter were of themselves sufficient causes (and causes which are present in almost all cases of fracture) was shown by the history of seven cases where the head sustained no local injury, but only suffered from general concussion.

The sensitiveness of the scars of the scalp seems to have been due to the bruising of the skin against the hard underlying surface by bullets or fragments of shell; and the scars following sabre-cuts were generally non-sensitive. The avoidance and removal of such scars would, of course, be eminently in place, and the same may be said of irritations of the dura.

It may be easily conceived that, besides fractures with displacement, cases of *healed* fracture would occasionally present themselves where — as a protection against epilepsy — trephining for the removal of suspected irritation of the dura would be justifiable.

Local injuries of the brain are recognized in these reports, as well as by all surgeons, as a possible cause of epilepsy, and these local lesions are liable to be beyond the reach of such surgical treatment as will remove the danger of epilepsy.

Dr. Keen¹⁴ has, to be sure, suggested the importance of the systematic removal of disorganized brain tissue, and this may mark a decided advance over Wagner's method,¹⁵ which consisted in removing only such parts of the brain as protruded beyond the dura, but it is too early to tell how thoroughly this plan can be carried out or with what results.

It is quite possible that we attribute too much im-

portance to the irritation at the seat of fracture as the cause of the subsequent epilepsy, instead of considering it as only one, though usually the chief of several contributive causes. At any rate the following facts should be borne in mind before we commit ourselves to a definite conclusion.

(1) Traumatic epilepsy is by no means always of the localized, so-called "Jacksonian" type. In many cases the loss of consciousness is as early and as sudden, and the first convulsive symptoms as widespread, as in ordinary epilepsy, and although the irritation of the dura at the seat of fracture might account for such attacks, we have no right to consider that it is the only or even the principal cause, so long as other possible causes are present, and this, in severe head injuries, is usually the case. As a rule, whether the skull be fractured or not, the brain is injured in a number of different parts, and the lesions of the brain near the seat of injury to the bone are liable to be much more extensive than the osseous fracture, and more or less independent of it.¹³

Either one of these various lesions, as well as the general injury which the brain sustains from concussion, are adequate causes of epilepsy, and it is not improbable that they may work together as contributive causes. Of course, even if this be true, we are not relieved from the duty of treating the original wound so as to secure a healthy and rapid repair of all the injured tissues, including the brain, so far as this is possible, but even after doing this we should be guarded in our prognosis. I shall refer again below to the important subject of the contributive action of several partial causes in inducing epilepsy even of the Jacksonian type.

(2) In many cases there is a considerable interval, often years in length, after the injury and before the epilepsy appears. Are we to assume that, during this period of latency, the hidden danger is silently drawing nearer, or is it more probable that while the irritation remains the same some new cause comes in to precipitate the outbreak? If the former is probably true, have we a right to assume that the series of nerve and brain changes resulting in the epilepsy are alone those which have the injury at the seat of fracture as a focus? Is it improbable that the inflammations and irritations starting from other foci of injury to the bone, membranes or brain, play their part in inducing the result? The answer to this question must depend upon the evidence with regard to the contributive influence of partial causes.

The immediate causes of epilepsy in these traumatic cases are so obscure and baffling that we ought to keep ourselves in a very catholic spirit during our search for them.

The only way to answer the question as to what are the significant alterations that occur before the attacks appear would be to tabulate all the morbid changes which do take place during this interval and that could possibly be causes of epilepsy, and then try to discriminate between their effects.

The physiological characteristic of the epileptic brain is generally believed to be that a greater or less portion of its ganglionic matter has acquired the habit of discharge under less than the normal stimulus; and

from what we know of the physiology of the nervous system it is fair to assume as probable that this liability to premature discharge might be brought about in three general ways: (a) by modifications of the nutrition of some particular centre or area of the brain; (b) by impairment of the inhibitory relations between different parts of the brain;¹⁴ (c) by an unnatural increase in the number or force of the stimuli tending to provoke the discharge of a given part of the brain. It is in this latter way that we may suppose "reflex" epilepsy to be caused, and we might class as "reflex" — at least for purposes of investigation — those epileptic attacks which are produced by the action of one part of the brain upon another.

In seeking the cause of epilepsy from injuries of the head, such as fracture with depression, we are too prone to look only at the lesion indicated under *a*, and fail to recognize sufficiently the more distant and obscure lesions falling under *b* and *c*.

I think there is reason to suspect that even when the "signal symptom" of an epileptic attack, in a case of head injury or cerebral disease is sharply localized, the responsibility for the outbreak should not always be laid exclusively at the door of the centre especially correlated with this "signal symptom," but that it often implies an abnormal condition of other parts of the brain, or of the brain at large. Certainly a number of cases have been reported¹⁵ of epilepsy of the Jacksonian type where careful examination has failed to reveal any lesion of the corresponding centres in the cortex.

We do not yet know the anatomical correlates of the epileptic state with enough exactness to make it worth while to describe them, but we may hope to arrive at them eventually by a conscientious study, macroscopic and microscopic, of the changes occurring in epileptic brains, especially during the pre-epileptic stage.

We do know already that during the latent stage of traumatic epilepsy the morbid changes developed by the injury (which may have several centres) are liable to spread laterally (Ziegler) as well as to become locally more intense; and we know further that localized epilepsy is liable to occur in brains which have been for a long time the seat of extensive and progressive morbid processes, as in the case of the post-hemiplegic epilepsy of children, and the epilepsy in paretic dementia. Again, we know that influences acting on sensory centres in the brain, such as fright, or fatigue, or toxic substances in the blood, may precipitate an attack, or even cause the disease. Löwenfeld¹⁶ calls especial attention to the fact that epilepsy having its starting point in the irritation produced by a tumor or other gross lesion, may remain latent until some other general cause comes in to increase the effectiveness of the local cause.

It is reasonable provisionally to suspect, therefore, that in the traumatic cases, multiple and spreading lesions which often exist, may contribute to increase the injurious effect of a predominant local injury.

It is undoubtedly true that purely local irritations of the cortex may excite epileptic attacks, just as these may be excited by localized electrical stimulation; but there is a body of facts, to which I think too little at-

¹³ Widespread hemorrhages and softening often ending in adhesive meningitis, are extremely common. See Bryant, Hunterian Lecture, Lancet, June, 1888; also Durat, *Traumatismes Cérébraux*; and an interesting case reported by Walter Channing in this Journal, July 8, 1888.

¹⁶ Loc. cit.

tention has been paid, which indicate that both in so-called idiopathic epilepsy and in some forms of traumatic epilepsy, the special and "localized" auras and convulsions are sometimes only the expression of a morbid condition involving a large cerebral area, or a whole hemisphere, or the whole brain, just as the feeling of anger may cause habitually, in one person a clenching of the fists, in another a frown or a paleness of the face, in another a sense of intellectual inhibition.

The character of the first, and, through the establishment of habit, of the subsequent outbreaks, would then be referable to a greater physiological excitability of one or another part of the brain, either native as in the case of the hand and face centres, which, as Hughlings-Jackson long ago pointed out, are so prone to be the first to discharge in ordinary epilepsy, or due to local disease or irritation of the brain or of the peripheral nerves as in traumatic and reflex epilepsy.

This principle has been abundantly established by both physiological experiment and clinical observations,¹⁷ but its practical significance as necessitating a modification in the application of the doctrine of the localization of functions in the brain,¹⁸ has not been sufficiently dwelt upon. The character of the most important pieces of evidence may be briefly indicated as follows:

(1) The experiments of Ferrier,¹⁹ of Bubnoff,²⁰ and Heidenhain, and other physiologists have shown that the movements of certain parts, such as the face, may often be excited by minimal stimulations of the cortex which are ineffective as regards other movements.

(2) It is asserted by Bubnoff that if an animal, in the course of an experiment, makes an accidental movement of a limb, the same movement is especially likely to be called out by the subsequent electrical stimulations of the cortex; or that if one limb is stroked or moved, movement is more likely to occur there than in other parts under a stimulation of given strength applied successively to all parts of the motor area.

(3) It is a remarkable fact, noted by Dr. Hughlings-Jackson, that the primary or "signal" (sensory or motor) symptoms of an epileptic attack in man occurs far oftener in the hand or face than in other parts, evidently because of the great physiological mobility and sensitiveness of these parts, so much so that I think such symptoms are of less value as indicating a localized irritation of the brain than the similar symptoms when affecting other less mobile parts, such as the leg or shoulder; that is, the hand or face may be thrown into convolution alone, or primarily alone, by an inflammatory process covering a large area. This principle applies both to traumatic and inflammatory, and to so-called idiopathic cases. I say so-called, because I believe that, pathologically considered, the traumatic and non-traumatic cases are often closely analogous.

Thus, to take one case out of many that could be cited, Dr. J. C. Warren operated recently, at my request, on a patient who, in consequence of a meningeal hemorrhage or meningitis which had occurred during a typhoid fever eight or ten years before, had had a transient hemiplegia followed by epilepsy.

¹⁷ Hughlings-Jackson and others.

¹⁸ I have called attention to some of its relations in a paper published in the Transactions of the New York State Medical Association in 1886.

¹⁹ Localization of Functions in the Brain. = Pfüger's Arch. 1889.

He had distinct auras, both sensory and motor, in the left hand, frequently without loss of consciousness, but at the operation the lesion was found to cover a good part, if not the whole, of the arm and face area. We snipped out a bit of the cortex, simply guessing at the hand centre, since no electrical response could be obtained, and for the next week the hand was paralyzed, obviously because its cortical arrangements were especially sensitive to damage, as they had previously been to irritation.

CONCLUSIONS.

(1) The causes of epilepsy are numerous; and we cannot hope in most cases to remove them all by early trephining and care of the wound, though these measures, and especially the removal of fragments, are probably very important.

(2) The local and the general injury of the brain are probably of prime importance, as causes of epilepsy, and are to some extent independent of fracture. The former may perhaps sometimes be treated as suggested by Keen, but the latter can only be reached by general treatment.

(3) The treatment of the general conditions of the brain, by cold and by prolonged, absolute mental rest is probably of great importance, and might perhaps be reinforced by other measures directed to the same end.

(4) The occurrence of localized convulsions or auras does not necessarily indicate limited local disease, to be removed by operation; since, on the theory that the disease is a general one, it would have to find some local expression. It is especially true that convulsions or sensory auras beginning in the hand or face are untrustworthy indications of the extent of the cerebral lesion, because the cortex corresponding to these parts has a high degree of irritability.

(5) Considering the long period that usually elapses after an injury to the head, before epilepsy declares itself, a period during which the patient may be perfectly well, it is reasonable to seek for some better term than "local irritation" to express the connection between the two events. We may fairly suspect that in most such cases a degenerative process goes on, which increases in extension and perhaps in intensity. Sometimes a neuritis, starting from the seat of injury seems the important link ["History of Franco-German War;" Nothnagel].

We know that such a progressive degenerative process as this is capable of giving rise to epilepsy of the localized type, independently of any gross local irritation, as in the case of epilepsy complicating general paresis, of ordinary epilepsy of certain types, and perhaps of epilepsy in cases of head injury without fracture, and of diffuse cerebral sclerosis. We know, further, that the removal of gross irritations in case of an already existing epilepsy of traumatic origin usually gives only a temporary relief. It is, therefore, reasonable to suspect that the state of impaired storage power on the part of the ganglion cells, which we call the epileptic state, is liable to be more widespread than the signal symptoms of the fit would suggest; that we have as often an instance of impaired inhibition or mutual support between different cerebral centres as of locally impaired storage power; that the fit is local in its first expression because the centre corresponding to the initial symptom was an especially irritable centre (for physiological or pathological reasons), and that the impulse to its discharge may originate else-

where, or be inoperative unless reinforced by other influences.

How near the epileptic condition may be to apparent health, that is, the latency of the epileptic state, is shown by the fact that epilepsy interchanges with other neuroses, and that the attacks may be brought on by slight causes. This, of course, is a reason for trying first to inhibit attacks for a time so as to check the habit, and, next, to keep away all possible exciting causes. This may constitute a sufficient reason for trephining even when we cannot believe that we can remove the cause of the disease.

(6) May not operation by trephining, for the sake of exploring the parts, be called for in case of patients presenting themselves for the first time after the fracture has healed, but before the outbreak of epilepsy — say within six months or a year? In some respects the tissues are perhaps in better condition for exploration, with the prospect of finding a delimited and removable lesion, a short time after the injury, though it is also true that degenerative processes may already have been initiated. This is a matter for further study.

TWO CASES OF TREPHINING FOR TRAUMATIC EPILEPSY.¹

BY PHILIP COOMBS KNAPP, A.M., M.D.,
Clinical Instructor in Diseases of the Nervous System, Harvard Medical School,

AND ANNE POST, M.D.,
Visiting Physician at the Boston City Hospital.

At the first Congress of American Physicians and Surgeons the subject of brain surgery excited much interest; at the second Congress the interest was as great, but three years' additional experience rendered the views of those who took part in the discussion distinctly less hopeful. This was especially the case with the question of trephining for epilepsy. The hope of cure from trephining in traumatic epilepsy, or from excision of the cortex in Jacksonian epilepsy, is now regarded as slight, although relief is not infrequently obtained. Some men, indeed, in the discussions took, without warrant, a thoroughly pessimistic position; the majority were not disposed to hope greatly from surgical interference. It therefore seems not unjustifiable to report the following cases, partly because failures should be reported as well as successes, and partly because they illustrate one or two points of interest.

Kate F., sixteen, single, a nursery-maid, presented herself at the out-patient department of the Boston City Hospital, February 17, 1890. She was born in Ireland. Her mother had been insane for eight years, her older sister was rather nervous; otherwise no hereditary taint could be discovered. The girl herself had always been in good health. The catamenia had been established two years before, and since then had been regular and without disturbance. Five years before coming to the hospital she was struck in the forehead with a stone, and was rendered unconscious by the blow. She was carried to a hospital in Dublin and lay unconscious for three days. She then recovered her senses, but she remained in the hospital for three months. After the injury she had strabismus for a time, but that passed away. Ever since the injury she has been subject to headaches; the pain being referred

to both sides of the forehead and to the top of the head, but, as a rule, it starts from the seat of the injury. She has a headache nearly every day, and it lasts several hours. She has also had a slight cough for some time.

In November, 1889, she had a convulsion. There was no aura; the head and eyes turned to the right, and the limbs worked. She frothed at the mouth, could not speak, began to stutter, something came up in the throat and then the head turned and she fell. She said that in some attacks she was conscious of what was going on, but she could not control the attack; in other attacks she lost consciousness. After the first attack she vomited. After the attacks she was sleepy and foolish. A month later, in December, she had a second attack. Since then she has had six more, about one attack a week, the attacks coming on in the morning.

Physical examination showed a stout, sturdy, rosy-cheeked girl with a small stellate cicatrix on the forehead, a little to the left of the median line, about an inch from the beginning of the hair, beneath which was an area of rough, irregular bone with some depression. Careful examination revealed nothing else remarkable. She was given fifteen grains of potassic bromide three times a day, and ordered a restricted diet. This was continued until March 5th, when it was omitted for two days, without orders. No indiscretion in diet was committed. March 9th she had a fit, and March 11th another. On the 11th she had a bad headache and cramps in the stomach. The bromide was ordered to be taken four times a day.

March 13th, she had another fit, and on the 19th another, in which the head and eyes turned to the right. She again, on the 19th, had headache and cramps. She was ordered to take thirty grains of bromide, three times a day.

March 26th, she reported an incomplete attack. The attacks have been preceded by marked vertigo.

April 9th. Three fits since last report.

The bromide having apparently failed to control the fits, I thought it advisable to lose no more time, and I advised her to enter the hospital for operation, which she consented to do, and on the 11th of April she was admitted to Dr. Post's service.

April 13th. Last night and this morning she had convulsions in which the head, eyes and mouth were drawn to the right. She was conscious, but she could not control the attack.

April 21st. She has been kept quiet in bed, and aside from a slight tonsillitis, she has been comfortable and there has been nothing to attract attention. This morning she had a convolution, followed by another at noon. These convulsions were general, the legs and arms becoming rigid, the muscles of the face and jaw twitching violently. They lasted four or five minutes. The last catamenia ceased a week ago; the convulsions have never been more marked at the menstrual period.

She had now had twenty convulsions, and bromide seemed powerless to control them. In many of them the signal symptom seemed to be turning of the head and eyes to the right. The centre for this movement is the motor centre nearest the seat of the injury. I thought it possible that a discharge, starting from the old wound, might extend first to this centre and then give rise to a general convolution. The thing to be done was clearly to trephine over the seat of injury,

¹ Read before the Boston Society for Medical Improvement, November 9, 1891.

and to remove, if possible, all cicatricial tissue. She was therefore trephined by Dr. Post on the 24th of April, a button of bone was removed, the dura and a portion of adherent brain-substance excised, and as much of the cicatricial tissue as possible was removed. Some thickened connective tissue was left in close proximity to the longitudinal sinus which could not be removed without cutting the sinus; elsewhere all tissue was removed down to healthy brain substance. The details of the operation will be given by Dr. Post.

The patient recovered well from the ether, but she had a little pain at the seat of the operation.

April 25th. Considerable headache this evening. The pupils are equal; the tongue is protruded straight. She was perfectly conscious. Five grains of antipyrine were given at night to relieve the pain.

April 26th. She felt better and had less headache. Her color was good, and she was bright and cheerful.

April 27th. Some headache, relieved by antipyrine.

April 29th. She felt very well, and was found sitting up in bed reading.

April 30th. She was allowed to sit up with blankets about her, but, instead of sitting still, she walked about the ward and talked with the other patients.

May 2d. Wound dressed. Perfect union by first intention. No redness or swelling anywhere about the wound. The stitches were removed and a small moist corrosive sublimate pad applied.

May 7th. General condition excellent. She was actively employed about the ward. No symptoms. Her health appears perfect.

May 9th. This morning she had a convolution, during which the head became fixed, the eyes were staring, and she frothed at the mouth. There was no twitching. In the afternoon she had another attack in which the face and all four extremities twitched. She was given fifteen grains of potassic bromide three times a day.

May 10th. Two convulsions to-day. The first was not seen until near the close; the second was general.

May 15th. One convolution since last note. Bromide increased to thirty grains.

May 21st. Doing well. Up daily about the ward. General condition excellent. She was put on a milk diet, and she had had no convulsions since the last note.

May 28th. Slight bromide acne. It is almost impossible to restrict the diet. No convulsions.

June 4th. General condition good. One convolution since last note. Bromide increased to forty grains.

June 11th. About ward. Two and one-half minimis of Fowler's solution given for acne.

June 18th. No more convulsions.

June 21st. General condition good. Wound firmly united, only a faint white cicatrix remaining. No more convulsions. Discharged; relieved.

She was seen at various times during the summer by Dr. W. N. Bullard, at the out-patient department, and he has told me that the convulsions then continued. She has now disappeared from observation.

Wm. H., eighteen, single, was referred to me by Dr. J. Richard Taylor, of Sag Harbor, April 28, 1891. His paternal grandfather died of phthisis, his paternal grandmother of apoplexy. His mother is very nervous, one of her sisters died of paralysis, another of

meningitis following influenza, a third of phthisis. The patient himself had been healthy until the age of twelve, when one day, while running with his head turned to the left side, he was struck in the right temple by the fist of a young negro who was chasing him. It is uncertain whether the negro had anything in his hand at the time. The boy was dazed for a time, the eye and forehead were badly swollen, but he made a speedy recovery, and went back to school that afternoon. There was no history of indulgence in tobacco, alcohol or venery, and venereal disease was denied.

In less than a year from the time of receiving this blow, the patient began to have seizures of various kinds. The account of the earlier attacks is not very definite. These attacks have increased in frequency. He now has three or four mild seizures a day, or even more, and, at the most, two or three severe seizures a week. He has been two weeks without a severe seizure, but within the last three months he has had forty-five severe seizures.

The severer seizures begin by turning of the head to the left; the left side of the face, the platysma and sterno-mastoid muscles, and the left arm twitch; the neck is more affected than the face. He sometimes bites his tongue, falls, loses consciousness and passes urine involuntarily. His physician reported that all the severer seizures began with a turning of the head to the left, and the left arm was usually affected. He frothed much at the mouth. Two weeks before coming to me, his physician saw him in a fit, in which he lost consciousness, ejected much froth from the mouth, and belched up much gas. In this attack he walked into the next room, came back and asked for medicine, went back and took it, and, as always happens, obeyed all the commands given. On returning to consciousness, three-quarters of an hour later, he had no memory of what had happened, and asked if the doctor had been there. He walked about with his eyes open and with the pupils moderately dilated.

In other attacks the head turns to the left, he froths much at the mouth, and he will take out his handkerchief with both hands in an aimless fashion. He will start and run, usually to the right with the head turned to the left, upstairs, or back and forth from one room to another. Sometimes he will recover promptly, at other times he will fall and have a convolution, with twitching of all the limbs, followed by rigidity. After these attacks he falls into a deep sleep lasting half an hour to two hours.

In other attacks he begins to stare, presses on the abdomen with both hands, and belches up wind. He talks and answers questions intelligently, but he has no memory of what takes place during the attack. As soon as the attack is over he feels and appears well, but if he has them very frequently he is languid and tired after them.

Finally the patient describes lapses of consciousness, lasting only a few seconds and not noticeable by bystanders. In these attacks the head does not turn. In the minor attacks he chews a good deal, but he does not bite his tongue. They are attended with considerable gastric disturbance, and there is much belching of gas after them. There is never any aura; the fits are about as frequent by night as by day.

Recently he has had a feeling of pressure at the seat of his old injury, especially when fatigued. The memory for every-day events is not as good as it used to be, but the memory for events of some time ago or

for book-knowledge is as good as ever. He is very fond of mathematics, but application renders him worse, so that he has given up school and study. He is a trifle more nervous and irritable than formerly. His general health is good, there is little headache and no visual disturbance, and he eats and sleeps well. No thoracic, abdominal or urinary symptoms.

Physical Examination. — Well developed, fairly nourished. The skin is thick and pasty, with an abundant fine papular eruption on the face, and to a lesser extent over the body. Mesaticephalic: long diameter, 19.2 cm.; biparietal diameter, 15.2 cm.; cephalic index, 79.16. Glabella to inion, 36 cm.; circumference, 56.7 cm.; measurement from one external auditory meatus to the other over vertex, 37.7 cm. Trococephalic and slightly plagioccephalic. A faint scar, the size of a pea, was seen on the right temple just at the beginning of the hairy scalp; there is a point near it which is sensitive to pressure. Pupils equal, 4 mm. in diameter, reacting to light and convergence. Ocular movements good. Field of vision and color sense normal, $vod = \frac{1}{2}$, $vo = \frac{1}{2}$. Fundus oculi normal. No deafness, tinnitus, earache or otorrhoea. Watch heard at five feet, au . Aural examination negative. Mobility and sensibility normal. Knee-jerk and plantar reflex normal. Dynamometer, R. 31, L. 33. Pulse 92-108. Examination of chest, abdomen and urine negative.

Medication had been faithfully tried for years. Hyoscine, hydrobromate and antipyrine had given some benefit, bromide had proved useless, iodide and mercury in small doses had seemed of benefit as a tonic. I agreed with his physician that trephining afforded a chance of relief, and I thought it best to have it done without further delay. He was accordingly admitted to the Boston City Hospital on April 29th.

April 30th. In the afternoon the nurse heard something fall, and found him on the floor with a clonic spasm of all four extremities and of the lower jaw; the spasm was not more marked in any one portion of the body. He frothed at the mouth, and after about two minutes he became rigid and lay in moderate opisthotonus for about three minutes; then he fell into a sound sleep. The head was shaved, the fissures and the tender spot were marked with nitrate of silver, and a corrosive sublimate dressing applied.

May 1st. The tender spot and the scar seemed to be very nearly over the centre for the movements of the head to the opposite side, and this movement was the signal symptom for the majority of the fits. He was, therefore, trephined over that spot by Dr. Post. Almost directly beneath was found a marked bluish white opacity of the pia, but the opacity and oedema extended in every direction under the edges of the trephine opening, so that it was clear that the lesion was diffuse. The details of the operation will be given by Dr. Post.

May 2d. He made a good recovery from the ether, and slept fairly, although he was restless the latter part of the night. In the morning he was comfortable. Temperature 99.5°, pulse 116. In the afternoon he complained of headache and restlessness, and of the tightness of the bandage, which was loosened. Temperature 101°, pulse 132. He was given hydrobromate of hyoscine (gr. $\frac{1}{15}$) at night.

May 3d. Very comfortable. Morning temperature 99.2°, pulse 100. Evening temperature 101.8°.

May 4th. Temperature lower. No convulsions. May 7th. Temperature has not risen again. No headache; good appetite; slightly constipated; sleeps well. May 10th. General condition excellent.

May 13th. Dressing removed. Wound found in perfect condition, healed by first intention. All the stitches, twenty-two in number, were removed. Not a drop of pus was seen. General condition excellent, and he complains of no trouble in the head. Dry dressing.

May 15th. Had a convolution.

May 20th. No dressing on head now. Yesterday he had four mild convulsions. He became unconscious for a few minutes, pulled at his lip, the pupils dilated, then he came to himself, and fell asleep. Up a few hours yesterday and to-day.

May 21st. Another convolution.

May 22d. Discharged. Not relieved.

June 4th. No attacks since May 26th. He has had thirteen since the operation. I saw him in one, which began by turning of the head to the left, and involved the left arm. He was given twenty grains of bromide of sodium and ten minims of fluid extract of cannabis indica, which seemed to control the attacks somewhat. A few days later he returned home.

A letter from Dr. Taylor, of the date November 1, 1891, gives further information:

"Mr. H. is at home, and I think has not materially improved since the operation. For three weeks after the operation he was apparently well, then had several days (two or three) in which he suffered from slight attacks characterized by temporary loss of consciousness, with profuse flow of saliva and unintelligible muttering and mumbling — each attack lasting from three to five minutes. Between each series there is an interval of ten or twelve days, in which he apparently enjoys very good health. Since the operation he has had ninety slight attacks and four severe convulsive seizures, in which the movements were noted on the left side, involving the muscles on the left side of the neck, chest and left arm. In running away on one occasion, he ran in a circular course to the left. His appetite is very good, the bowels act well, and he rests well, though a light sleeper. He devotes too much time to thinking about his condition, though I keep him busy with out-door pursuits as much as possible. He uses Brown-Séquard's mixture of iodides and bromides and fluid extract of cannabis indica."

These two cases may serve, perhaps, as a text leading to a discussion of the propriety of trephining for traumatic epilepsy. The possible scope of the operation has been extended of late, so that there are now two questions to consider: the propriety of trephining in cases where epilepsy has declared itself, and the propriety of trephining in cases of head injury as a means of preventing epilepsy.

The operative proceedings in cases of epilepsy have been further extended, in that operation is undertaken not only for the elevation of depressed bone, the removal of cicatrices, etc., but also, in Jacksonian epilepsy, for the excision of the apparently intact cortical centre from which the discharge arises.

Excision of the cortex has been done in comparatively few cases, and the results, as a whole, have not been very satisfactory. In several cases, however, temporary relief has been obtained, and in a few cases the fits have not recurred up to date, a period, however, of only two or three years. Even such a limited

percentage of success, however, renders the procedure justifiable in severe cases.

Trephining for the purpose of removing depressed fragments, cicatrices, etc., is an operation of much longer standing and of a less serious character. Cases are on record showing relief and even recovery following such an operation so as to render its performance perfectly justifiable. It may be well, however, to consider some of the factors which render the success of either operation doubtful.

The theory advanced by Hughlings-Jackson, that local irritation of a cortical motor centre may lead to a motor discharge from that centre, and perhaps from others near it, is well known. Following upon it came the corollary to remove the irritation from the centre as a prevention of subsequent motor discharges.

In cases of injury to the head, however, we may have two factors: first, a general commotion of the contents of the cranium, and, second, a local injury of the skull and the brain beneath it. The first factor is always present, the second is not constant.

We know that such a commotio cerebri may give rise to various diffuse structural changes in the brain, and, as a result of such changes we may have epilepsy. It is, moreover, now well-established that partial epilepsy, of the so-called Jacksonian form, may be the result of diffuse changes, of lesions remote from the affected centre, of poisoning, as in uremia, and of various unknown diffuse molecular (?) changes as in true epilepsy and hysteria. Commotion is therefore a possible causal factor in all cases of traumatic epilepsy, and if it be the cause, the removal of any local lesion will be powerless to effect much relief. My second case shows clearly a diffuse lesion, giving rise to partial epilepsy, and due, not improbably to the diffuse, rather than to the local effects of the blow, in what was probably, from its heredity, an invalid brain.

In other cases we may have epilepsy as a result of the local irritation, although, as the general commotion can seldom be excluded, this is less absolutely certain. Granting the fact, however, we find, not infrequently, a history not unlike that of my first case. A fairly healthy brain receives a local injury, and, for a long time, resists its effects. Finally the resistance yields and an epileptic attack follows. In the present case the brain resisted four years and a half. In that period there is time for various secondary processes (inflammatory changes starting from the seat of injury, secondary degenerations of association tracts, etc.), to develop. Hence, by the time the epilepsy has manifested itself, the other diffuse changes are well-advanced. Although the local irritation may be removed soon after the epilepsy appears (after only twenty seizures, as in this case), the secondary changes may keep up the trouble, and the operation may prove futile. With an invalid brain the resistance is less prolonged, there is therefore less time for secondary changes, and the removal of the local irritation may thus give more relief.

It is unfortunately by no means easy to determine how far either one of these factors preponderates in the causation of epilepsy in the individual case, nor can we, as yet, decide whether the trouble be due to general commotion or to local irritation. Hence every operation must be merely tentative, and the result, as follows from what has been said, will always be doubtful and not infrequently negative.

In view of the gloomy prognosis of traumatic epi-

lepsy, even after an operation, the question of preventive treatment by early operation naturally arises. If epilepsy be due to a local irritation, and if that irritation be promptly removed before the secondary changes above referred to have set in, the chances for recovery are naturally much greater. The risks of such an operation are, of course, comparatively slight, although statistics are lacking to enable us to give exact figures. Hence, a year ago, Horsley urged that every fracture of the skull be immediately trephined, and Agnew, at Washington, assented to that view so far as to urge that every depressed fracture be trephined.

It is certainly justifiable to do much to prevent epilepsy, and in some cases this procedure will probably be successful. Most men to-day, I think would trephine such a case as my first one at once, and, if this had been done, I think the epilepsy would have been prevented. In my second case, however, no one would have thought of trephining, and I doubt if early trephining would have done much good.

We lack information on two important points. The first is how many cases, the second is, what cases of fracture of the skull will be followed by epilepsy. From May 1, 1882, to January 1, 1891, 122 cases of fracture of the skull have been discharged relieved from the Boston City Hospital. During the same period 184 new cases of epilepsy have presented themselves for treatment in the out-patient department. These figures have some slight value in showing the relative frequency of the two conditions. I have certainly seen one-third and probably one-half of the epileptics. Of those that I have seen only a small proportion, not over ten per cent., could be regarded as traumatic. My figures are of course vague, but they would lead us to suspect that only a minority of the cases of fractured skull become epileptic.

Dr. J. J. Putnam has recently called attention to the possibility of epilepsy being due to the diffuse changes above referred to, and he has also emphasized the fact that in many cases, even of depressed fracture, the depressed inner table of the skull presents a smooth, rounded surface, which cannot act as a local irritant.

Considering, then, the probability that a general commotio cerebri is a prominent factor in the causation of traumatic epilepsy, that many fractures do not give rise to local irritation, and that, probably, a majority of the cases of fractured skull are never followed by epilepsy, I am disposed to believe that preventive trephining is hardly warranted unless there be distinct cerebral symptoms at the time, which would indicate its performance independently of any consideration as to subsequent epilepsy, or, in other words, that preventive trephining, *per se*, is not, as yet, justifiable. If we could tell what cases are likely to be followed by epilepsy it might be different, but, as yet, we have no means of deciding upon this point.

SURGICAL DETAILS, BY DR. POST.

It seemed to me, at first, that the operation was so simple that there was nothing to say upon the purely surgical details; but thinking it over a little made me feel that when it had become possible to remove a piece of bone from the skull with a bit of the meninges with an assurance of primary healing without special constitutional disturbance, that there might be something worthy of mention in the methods.

Briefly, the details of the two operations were as follows:

Kate F. entered the hospital on April 11, 1890. Soon after entering she developed a tonsillitis, and on the 17th the temperature was 101.8°. The operation was done on the 24th; her temperature being normal in the morning of that day, before the operation, and 99° in the evening, after the operation. On the next evening it reached 101.2°, gradually falling from that time, it became normal again on the fourth day.

Preliminary to the operation, the scalp was shaved and cleaned; a semicircular flap with the scar in the centre was cut and turned back; a cicatrix in the bone was exposed, which was included in the trephine button one inch in diameter which was removed.

The bone was unusually thick on one side, and was united to the dura in the centre. When separated, there was slight bleeding from the torn dura. A piece of the membrane, the size of the trephine hole, was cut out, which seemed thickened, and was adherent to the brain beneath. The small adherent portion of brain substance was removed. The wound was irrigated with boracic acid solution and closed with silk sutures, and a baked dressing applied. No drainage-tubes were used.

On the fifth day (29th), the patient was found sitting up in bed and reading. On the sixth, she was allowed to sit up in a chair with blankets, but walked around and gossiped with the other patients.

The trephine button was an exceedingly interesting one. It was, as mentioned, double as thick on one side as on the opposite. On section, it showed a sclerosis of the bone at the point of injury, which entirely obliterated the diploë. A minute canal ran from the outer to the inner surface. The inner face of the bone was as smooth as though it had never been injured. No operation at the time of the injury could have left a smoother surface.

W. L. H., aged nineteen, was operated on May 1, 1891. His scalp was shaved and thoroughly scrubbed. A semicircular incision was made about the spot previously decided upon. Three buttons, five-eighths of an inch in diameter, were removed and united by bone-forceps, making a hole some two inches in diameter. The bone was rather thin, but there was a troublesome hemorrhage from the diploë, which was most easily controlled by a wax or putty made after a suggestion of Mr. Horsley. The flap was sutured without drainage-tubes, and a dressing was applied of baked gauze, the inner layers of the dressing being moistened with corrosive sublimate solution, 1 to 3000.

On the evening of the third day his temperature was 101.2°, the highest point reached. On the seventh day the record reads, "Temperature has come down steadily. No headache."

On May 13th the dressing was removed for the first time, and the wound was found in a perfect condition. It was entirely healed by first intention. All the stitches, twenty-two in number, were removed without disclosing a drop of pus. His general condition was excellent, and he complained of no trouble in the head.

In both cases the semicircular flap was used, which differs very decidedly from the old crucial incision. It is much easier to control, a single pair of forceps holding it out of the way instead of four, as in the crucial incision. It gives better access to the field of operation, and when the operation is done it covers the wound completely, like the lid over the top of a flask;

but its great advantage is the fact that the edges come together perfectly giving a better opportunity for immediate union. Another advantage of the flap is that it allows the raising of the periosteum, with all the soft structures, so that the periosteum is preserved comparatively uninjured, and replaced with ease in its proper position.

Such a flap, like any incision in the scalp, is liable to bleed freely; and if an operation is prolonged, as it was in the first operation where the bit of bone to be removed had sides of very unequal thickness, it is worth while to take some pains to control the loss of blood, which amounts to a good deal in the course of a long operation. With our modern hemostatic arrangements it is comparatively easy, but it is necessary to think a little about wounding the flap, as one is extremely anxious to get first intention. For that purpose I took pains never to clamp the whole thickness of the scalp, but where it was impossible to secure the artery in any other way, a stitch was taken and tied tightly, compressing the artery in that way, the stitch afterwards being removed, of course.

In enlarging the trephine wound, instead of taking out a second or third trephine button; I prefer to take out a single button, and enlarge the wound with the gouge forceps. It can be done with a pretty thick skull, but hardly possible with a skull of the thickness of the first button I showed.

The putty, suggested by Mr. Horsley, the exact formula of which I do not know, but an imitation of which has been made, is extremely convenient in controlling the bleeding from the skull itself. It is very desirable to have an unobstructed view of the meninges after the bit of bone has been removed, and by stuffing the bleeding points of the skull with this wax one not only controls the hemorrhage, but secures an unobstructed field.

In closing the wound it seems to me that it can never be necessary to sew together the membranes. It would be a much greater disadvantage to leave a stitch beneath the skull than any possible advantage that could accrue from it.

The replacement of bone after the operation is a question that is sometimes considered. I did not do it in either of these cases, nor in any of the other cases I have trephined for traumatic epilepsy. It seems to me that the object to be attained by the operation is the removal of that bone, and once removed there is no object in replacing it, even if nothing is found beneath it, and I cannot but think there may be an advantage in giving a little extra space for the brain to expand.

I did not put any drainage beneath these flaps, but closed them tightly. I will not say no drainage should ever be used. If a great deal of damage has been done, and one expects considerable hemorrhage or leakage of any sort, drainage may be desirable; but ordinarily speaking, where there has been a clean wound and comparatively little damage done, I prefer to close the wound immediately without any drainage at all. The advantage of no drainage was illustrated particularly in the second case, where the patient went thirteen days without any dressing. Had there been a drainage-tube of any sort, a dressing would certainly have been necessary in a much shorter time. But when I say that these wounds were closed tightly, perhaps I ought to explain that I took pains in these cases to carefully adjust the flap so that first intention was

possible everywhere, but at the same time I did omit a stitch or two, so that if there was any oozing or anything that needed to find exit, there would be a weak spot in the suturing where it could find exit more easily. The wounds were then covered closely with a baked dressing that is highly absorbent, so that little vacant space is left to fill with serum, and whatever oozes out is quickly taken up by the dressing.

The subsequent care of the cases was quite simple. I must confess that the second of these cases gave me a little anxiety for a day or two, as he gave me the impression of being quite sick during the time. In the first case the only anxiety was to know how long to keep the girl in bed. She would have been glad to get out of bed the second day, and when she was, with hesitation, permitted to sit up on the fifth day, she surprised us somewhat by running about the ward in the manner that has been mentioned. Whether any possible damage could be done to a patient by getting up and running about too early is a question in my own mind. I kept the girl quiet as long as I could, but at the end of a week she was practically beyond control. The young man I kept in bed much longer, with the intention that if there was any advantage to be gained from quiet after the operation, he should have it.

The danger of the operation seems to be very slight indeed. I suppose it would be the common feeling of all surgeons at present that while no operation should be done unnecessarily, there is practically no more danger in trephining an adult in good health than in going through the soft parts.

OCULAR HEADACHES.

BY FREDERICK E. CHENEY, M.D.

Instructor in Ophthalmoscopy, Harvard Medical School; Assistant Surgeon to the Massachusetts Charitable Eye and Ear Infirmary; Ophthalmic Assistant to the Out-patient Department of the Massachusetts General Hospital.

If a patient complains of headaches, pain in the eyes and poor vision, the probability of a refractive error being the cause is now very generally recognized. If, however, the sight is apparently normal, there is little or no discomfort in using the eyes for near work; and especially if the headaches are not frontal, an ocular defect as a possible cause does not usually receive much consideration. It is, nevertheless, a fact that a large number of patients, who have good sight both for distance and near, and who are able to read and sew for hours at a time without discomfort, suffer from migraine and neuralgic headaches, frontal, temporal, occipital and general, that can be entirely relieved by the correction of some refractive or muscular defect.

Strümpel, in his "Text-Book of Medicine," after mentioning a number of remedies that can be tried in the treatment of habitual headaches, concludes the chapter with the following paragraph:

"We can sometimes do the patient good service with remedies mentioned, but in other cases the evil obstinately defies all attempts at cure. Then, however, the patient has still the encouragement left that the disease often ceases at least spontaneously in advanced age, after lasting for years and years."

The oculist is consulted by many patients who give a history of past headaches that have lasted for "years and years," and that have finally ceased spontaneously.

They usually present themselves between the ages of forty-five and sixty, and are found to have a moderate degree of astigmatism or hypermetropia, the correction of which earlier in life might have prevented years of suffering from habitual headaches. It is not difficult to understand why reflex ocular headaches should cease at this time of life. The emmetropic eye, as we know, sees distant objects clearly without any effort of the accommodation, and at the reading distance by increasing the convexity of the crystalline lens three dioptres. The hypermetropic or astigmatic eye, on the other hand, finds it necessary to accommodate for distance as well as for near, if clear vision is to be obtained. As an illustration, if an individual with a hypermetropia of three dioptres sees distant objects clearly, he must use three dioptres of accommodation, — the amount used by the emmetropic eye in reading, — and six dioptres, or double this amount, for his near work. In early youth, when the accommodation is most active, this extra work is accomplished without much difficulty; as he grows older, the effort to maintain clear vision becomes greater and greater, in consequence of the natural failure of accommodation until, with advancing years, the time comes when the power is not strong enough to overcome the defect, and soon ceases to attempt it. So long as the struggle for clear vision continues, so long may we look for headaches or other reflex troubles as a result. With a cessation of this struggle what is more natural than that "the disease" should "cease at last spontaneously after it had lasted for years and years." Another interesting point in connection with the fact, that symptoms of eye-strain are present only when an attempt is made to correct the defect, is, that individuals having very high degrees of hypermetropia or astigmatism are much less liable to pains in the eyes and headaches than are those having small and moderate degrees. A patient with four or five dioptres of astigmatism will consult an oculist, in a large majority of cases, not because he has asthenopia or severe headaches, but on account of poor vision. In other words, he has found it impossible, even by the greatest effort of the accommodation, to obtain clear vision for any length of time and has ceased early in life to make the attempt. On the other hand, we see patients with one-half or three-quarters of a dioptre of astigmatism who see perfectly well both for distance and near, but who do so at the expense of an extra strain on the accommodation and who often suffer severely in consequence.

The following cases which I report are not exceptional, but will serve to emphasize one or two points which I wish to make prominent in this paper, namely, that patients may suffer for years from ocular headaches and yet have little, if any, local eye symptoms that will suggest their origin. The sight may be good, they may be able to use the eyes constantly for near work with little or no discomfort, and in some cases the pain may be confined principally to an area more or less remote from the eyes.

CASE I. A lady, forty-five years of age, was first seen April 28, 1891. She has always had headaches, usually as often as once in two weeks, frequently two or three in a week. During school life had sick headaches, but the last few years they have been mostly neuralgic. Pain usually begins over the eyes and becomes general, but is sometimes confined to occipital region. She has always seen perfectly well for distance and near and the eyes have never ached until

within the last year or two. An examination under homatropine gave the following results: vision of the right eye normal, hypermetropia two and a half dioptres, vision of the left eye normal, hypermetropia three and a quarter dioptres, no insufficiency or other ocular defect. Glasses correcting the refractive trouble were ordered for constant use. The patient reported after using glasses for five weeks, that there had been no headaches or pains in the eyes during that time. She was again heard from five months later, and there had been no return of the headaches.

CASE II. A gentleman, fifty-two years of age, consulted me July 20, 1889. The trouble complained of was poor sight for distance and near. Until within the last two or three years, he has seen perfectly well for distance, but has used glasses for reading for about seven years. The eyes have never ached or given other signs of being strained. He has been subject to severe neuralgic headaches all his life. Until lately he has had from one to three attacks a month, now much less frequent and not as severe. They are usually at the back of the head, the pain extending into the neck and shoulders, sometimes at the side of the head, rarely over eyes. Upon examination he was found to have hypermetropia of one and a quarter dioptres in the right eye, and one and three-quarters in the left. With correcting glasses, distant vision was normal. No insufficiency or other ocular defect. Glasses correcting the hypermetropia were ordered for distance and appropriate ones for near work. There is little in this case that would suggest eye-strain as the cause of the neuralgia, but the probabilities are, that if glasses correcting the refractive error had been worn constantly from early youth, the patient would have been saved much suffering. The good vision he has enjoyed for years has been obtained by overworking the ciliary muscle. The inability to do this work results in a failure of sight, at about which time there is also a marked decrease in the frequency and severity of the headaches.

CASE III. A gentleman, twenty-five years of age, book-keeper, first seen February 2, 1890. He has had severe headaches for a number of years, top and back of head. Has dull pain in the head most of the time. Lately has had dizzy spells and occasional pains in the eyes at night. Sees perfectly well both for distance and near. Upon examination, under homatropine, he was found to have three-quarters of a diopter of hypermetropic astigmatism, each eye, axes vertical. Eyes otherwise normal. Glasses correcting the astigmatism were prescribed for constant use. The patient reported three months later that the headaches and dizzy turns had ceased soon after he began to use glasses and had not returned.

CASE IV. A gentleman, forty-one years of age, first seen May 6, 1891. He had had headache for a number of years, frequent, but not of sufficient severity to confine him to the house. Usually wakes with a headache if he has been to the theatre the night before, or read late. The pain is frontal and in the top of the head. Has always been a great reader. Sees perfectly well, and eyes have never ached until lately, and not enough now to prevent his using them a number of hours daily for near work. Upon examination he was found to have a quarter of a diopter of hypermetropic astigmatism in the right eye, and double this amount in the left, axes vertical. Glasses correcting the defect were prescribed for constant use. He was

heard from about four months later, and there had been little or no headache since using them.

It is unnecessary to mention other cases, which would simply be a repetition of histories that are familiar to every practitioner. All functional headaches do not of course result from eye-strain, but eye-strain is a sufficiently common cause to make an examination of the eyes advisable when internal or other treatment does not result in a cure after a reasonable length of time. A dose of phenacetin, antipyrine, or of various other remedies will often result in a cessation of pain, but they may also prove of equal value in controlling the neuralgic pain which accompanies iritis; and yet the iritis, the cause of the pain, is probably neither better nor worse for such treatment. It is impossible to say just what per cent. of functional headaches result from eye-strain, but I should be very much surprised, if out of one hundred unselected cases, at least one-half of fifty per cent. were not greatly benefited or entirely relieved by the correction of some refractive or muscular defect. An occasional headache may, of course, occur in the most pronounced ocular type, even after the trouble is fully and actively corrected, for the reason that the proper position of the glasses before the eyes is not always maintained, and their constant use is even neglected, but that the relief will be such in this per cent. of cases as to leave little doubt in the minds of the patient and physician as to the origin of the trouble, I most certainly believe.

To show that this is not merely the enthusiasm of a specialist, I may say that my friend Dr. G. L. Walton has recently assured me that in cases complaining of cephalgia, and especially migraine of long duration, after eliminating organic diseases and toxic and syphilitic influences, his first suspicion is that an error of refraction exists, a suspicion so often verified by experience, that he considers the estimate above named a very conservative one.

It is not difficult to see why ocular defects should be such a potent factor in the causation of headache. In our present civilization, where the ability to read and write is so general, and where the demands made upon the eyes for near work are so rapidly increasing, we find ourselves provided with visual organs that are by no means perfect in their optical construction, though well adapted to the requirement of the savage and even to the larger proportion of our ancestors of a hundred and fifty years ago. To the student, the bookkeeper or the sewing woman, the ability to see distant objects clearly is but of secondary importance; the thing most to be desired is the ability to see near objects clearly, with as little muscular effort as possible. The individual with a myopia of three dioptres would seem, therefore, best fitted for an occupation requiring the long-continued use of the eyes in near work, in that no accommodation effort is necessary for clear vision at the reading distance.

In conclusion, I wish to say a word in regard to the advisability of correcting ocular troubles in the more serious forms of functional nervous disturbances. To say the eye-strain is a very frequent cause of epilepsy and chorea, would be to mark one's self as an enthusiast; but I am thoroughly convinced that many cases can be relieved indefinitely by a correction of some refractive or muscular defect. The expression "relieved indefinitely" is used advisedly, in preference to "cured," for the reason that eye-strain cannot be regarded otherwise than as an exciting cause in precipi-

tating the nervous affection, a predisposition to which already exists. If an epileptic is found to have a refractive error, and if a correction of this error results in a cessation of the attacks, the treatment cannot be regarded as valueless because the trouble ultimately returns. It should rather be regarded as a proof that reflex irritation is capable of precipitating the attack, and should lead to a careful search for other possible exciting causes.

Clinical Department.

A CASE OF FUNCTIONAL MONOPLEGIA IN A MAN, DUE TO TRAUMATISM: RECOVERY.

BY JOHN G. BLAKE, M.D.,
Visiting Physician, Boston City Hospital,
AND MORTON PRINCE, M.D.,
Physician for Nervous Diseases, Boston City Hospital, Out-patient
Department.

THE case which we are about to report should be of interest to the general practitioner as well as to the neurologist, because it shows the degree to which paraparesis may develop after an injury and yet be functional, and the possibility of recovery from such a condition. The case is also interesting in many of its details, being a typical example of so-called hysterical or functional paralysis of the type made classical by Charcot. The patient met with the accident in the following way: He was standing on a board which was lying upon the ground when one of the derricks of the new court-house fell, striking one end of the board and tilting the other end violently into the air. The man was thrown over backwards and received a violent shock although no external signs of injury at the time could be detected. The date of the accident was November 9, 1887.

The physician who saw him immediately after the accident, stated that the patient was brought to his office on the back of another man, and that he (the patient) said he had been hit on the leg and back and he could not move his leg without pain. There were no visible wounds on his body.

Dr. Blake saw him one month later; at that time he was in bed. There was entire loss of power and sensation in the right leg, and he complained of distress and pain in his stomach for which he required opiates. This condition had existed since the accident, but the gastric symptoms about this time were worse.

He was seen by Dr. Walton April 22, 1888, five months after the accident. Dr. Walton's notes, which he has kindly given me, show that his condition at this time was practically the same as when seen later by the writers in consultation, excepting that pain in the stomach, headache, and pain in the right leg and back were more prominent symptoms, and were said by the patient to be more severe than immediately after the accident. Dr. Walton also noted an area of numbness in the lumbar region. This was not afterwards noticed, if present.

The writers found his condition January 30, 1889, fourteen months after the accident, to be as follows: The right leg was paralyzed. This paralysis was absolute, or nearly absolute, so that he had no control over it whatever. There was also complete loss of the tactile sense and of the sense of pain from the knee down. The most severe pricking and pinching was not felt, and the strongest faradic current was only

slightly appreciated on this part of the leg. The man walked with crutches, dragging his right foot along the ground. The muscular sense of the right leg was also lost. More careful examination, however, showed that the disability was more extended than this, and although the paralysis and anesthesia appeared to be limited to the right leg there was a general weakness of all his muscles more marked on the right side, though not amounting to absolute paralysis. And although the absolute anesthesia was sharply limited in a typical way by a line at the level of the knee, yet, when tested by the asthesiometer, it was easy to make out that there was a blunting of the sensation over the whole right side. On the front it was limited by the median line of the body (limiting line of the back not determined). More than this, there was impairment of all the special senses, the impairment being more profound on the right side. There was great loss of acuteness of vision in both eyes, so that he was obliged to hold a watch and large printed letters close to his eyes to see. There was absolute loss of the perception of colors in the right eye, and the left only recognized red and (temporarily) green. There was moderate limitation of field of vision in both eyes. The hearing of the right ear was about $\frac{1}{3}$, and of the left $\frac{4}{5}$ tested with the watch. The drums were normal.¹ Taste was blunted on the right side of the tongue and smell on the right side of the nose.¹ His general condition was that of great debility; he was pale, anaemic and generally weak. He was very easily tired, as, for example, by the examination.

Dr. C. F. Folsom also saw this case in consultation with the writers and all agreed it was one of hysterical paralysis. It may be here mentioned that the man was in no sense of the word hysterical or emotional in the popular sense, a condition which is often thought to be essential in this form of paralysis.

Our reasons for diagnosing functional and not organic disease were as follows: Although there was loss of the plantar reflex on the right side, the cremasteric and abdominal reflexes were present and the knee-jerk, contrary to the customary condition in organic disease of this duration, was absent on the right side, although present feebly on the left. Nor was there any rigidity or spastic condition of the paralyzed limb, but the leg was limp and flaccid. It will be remembered that a monoplegia due to organic cerebral disease must be caused either by a very limited lesion of the internal capsule or by disease of the cortex; in either case, when such paralysis is absolute, and after it has continued for any great length of time, descending degeneration takes place along the motor paths and a spastic condition of the limbs result with increase of the deep reflexes.

The gait is also characteristic owing to the spastic condition of the leg. If this case were to be attributed to such cerebral disease the implication of the special senses would require its localization in the neighborhood of the internal capsule. But lesions of this region do not produce amblyopia of both eyes, but hemiopia. This is due to the involvement of the optic radiations, that is, the prolongations of the optic nerve on their way from the optic thalamus to the occipital lobes.

Although there is much dispute amongst physiologists, whether there is any region of the cortex, de-

¹ This is stated from memory, no note having been made at the time though these particulars were included in the examination.

stinction of which produces amblyopia in both eyes, and although Ferrier maintains that lesions of the angular gyrus has this result in monkeys and in dogs, there is no clinical evidence that such is the case in human beings or that when such amblyopia occurs it is not due to functional disease. The way in which this man dragged his foot was also very characteristic and the absence of paralysis of the face, though not of great importance, had some significance. It is an interesting fact that, although there was no atrophy of the paralyzed muscles, they did not respond as well to the faradic current as did those of the sound leg. As a suit for damages was in progress, it was agreed, in order to eliminate any suspicion that might be raised regarding malingering, that the patient should be etherized. He submitted to this test, but no movement could be detected in the paralyzed muscles. A verdict was given by the jury for \$6,000.

Shortly after the trial the patient sailed for Italy. It so happened that a friend of the claimant and one of the witnesses also went to Italy about this time. A short time ago she returned and reported to me that she had been to see the patient at his home and found him apparently perfectly well. She said that they had taken long walks together, climbed hills, etc.; that he had recovered the loss of his eye-sight and was practically well. She said that he told her that his recovery began to take place shortly after his arrival and was rapid. This was about three months after the settlement of the case.

Cases like this one are not very uncommon and form quite a percentage of the cases that come into the courts. The claim is generally set up that they are due to organic disease and that they are incurable. The ending of this one illustrates the possibilities of a favorable issue in a comparatively short space of time, although it must not be denied that many such cases persist in *statu quo* for a great length of time.

ADENDA.

The skin of the right leg was colder to the touch and by the thermometer than that of the left. The grasp of the right hand ranged from twelve to twenty degrees, of the left from twelve to thirty, by the dynamometer. No ataxia. Both thighs and legs measured the same. The left eye perceived yellow and green as white or light shades, blue and violet as black. He complained of steady dull pain in the abdomen between epigastrium and sternum.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

O. G. SEARS, M.D., SECRETARY.

REGULAR Meeting, Monday, November 9, 1891,
the President, DR. FREDERICK I. KNIGHT, in the
chair.

DRS. P. C. KNAPP and ABNER POST reported

TWO CASES OF TREPHINING FOR TRAUMATIC EPILEPSY.¹

DR. JAMES J. PUTNAM read a paper on
THE RELATION OF EPILEPSY TO INJURY OF THE
HEAD.²

DR. J. C. WARREN: I think the gentlemen who have already spoken have covered the ground so thoroughly that I have nothing special to say on the general subject.

From the surgeon's point of view the question of interference at the time of the injury is one, of course, of great importance, particularly after what has been said by the gentlemen this evening. We see what is possible to result from local irritation, and we have got to determine in a case whether there is sufficient local trouble which is likely to remain and be progressive afterwards to authorize us to interfere. I do not feel, as a result of my experience, authorized to interfere in cases of simple fracture, even if there are some localizing symptoms at the time, unless those symptoms have a certain amount of permanency showing perhaps the presence of clot underneath the point of injury. But if there is any depressed bone, it seems to me that I should not hesitate to interfere in any case, whether there were localizing symptoms or not. It seems as if under those circumstances one ought to make an exploratory incision through the bone and see how much injury there has been to the inner table and perhaps to the membranes of the brain. We may have little or no trouble, but we have done little or no harm to the patient, removing simply a button of bone. We may have a greater amount of injury to the inner table than is apparent to the outer table, and may have one of those sharp points which is going to be a source of meningeal and perhaps cortical irritation. It is not necessary in many cases to have depression of the inner table in order to produce considerable irritation. We may have persistent headache and perhaps symptoms pointing to meningeal irritation and perhaps irritation of the brain itself as a result of direct injury to the bone, not simply a contusion of the bone, but perhaps a depression of the outer table. We may have a localized ostitis, which may communicate itself to the meninges, and may be the result of thickening of the bone and some dural irritation, which may lead subsequently to the necessity of an operation. I have such a case in mind where a boy was kicked by a horse, and where there were two depressions something like those shown in the button Dr. Post has removed, and with some irregularity in the bone. In this case there was persistent headache of such character as to prevent the young man from pursuing his studies, which has been entirely relieved for a year now by removal of a button of bone. The dura was found adherent to the bone at the point of trephining. Possibly in those cases there is some anchoring of the brain, that is, adhesion of the brain to the dura, and irritation every time there is change of the volume of the brain, due to variation in the circulation or whatever movements are possible. That condition known as anchoring of the brain gives rise to considerable irritation, and is one to be thought of when we have to settle the question of an operation.

In regard to the details of the operation, they are so familiar that I think there is not much to be said. Dr. Post has already described that. I would merely mention the points in which I have acted slightly differently. I am in the habit of suturing the dura. I do not know whether in some cases hernia of the brain might result if this were omitted; but it brings the parts back perhaps a little more to their natural condition than if suturing is not done.

In regard to the replacement of the bone, I have done that in one instance only in these operations,

¹ See page 5 of the Journal.

² See page 1 of the Journal.

and that with entire success. It seems to me as if in cases where a considerable portion of bone was removed, it was of advantage to have a restoration of the cranial vault after the operation. It gives a little better security to the individual afterwards, although large holes from the removal of the button have been made without subsequent inconvenience to the patient. I had a relative who was operated on by Dr. John Warren, in his youth, for compound depressed fracture of the skull. A large number of fragments were removed. There was a space perhaps three by two inches in the temple. That gentleman lived to be over eighty, and never had the slightest trouble or inconvenience from that soft place in his head.

The question of drainage is an interesting one to surgeons, and I am inclined to agree with Dr. Post that drainage is not necessary in these cases. I have tried both ways, and find they do as well without. My custom, following Dr. Keene, is to leave a slight strand of gauze between the stitches for twenty-four hours, to let out the primary oozing of serum that takes place after any operation. I think that patients are a little bit more comfortable after a precaution of this kind than without. The symptoms of pressure are less. Possibly it may save an attack or two of epilepsy.

In regard to the after-treatment, it seems to me it is important that patients should be kept quiet. I do not understand the modern departure from the old custom, which was that patients should be watched carefully after head injuries for a month at least. Dr. Keene, in one of his first cases, allowed the patient to walk a half-mile on the fifth day, and many patients are up and about in five days. No doubt that can be done, and it is an interesting testimony of the brilliant results of aseptic surgery; but at the same time it seems to me that the brain needs rest after such operations as this, where it has been exposed, and particularly where irritation seems to threaten such grave results, a considerable period of time should be allowed to elapse before any excitement should be produced. I am in the habit of keeping the patient pretty quiet for two or three weeks after the operation.

There was one interesting point in the discussion on this subject in Washington in respect to the after-treatment in these cases, namely, that bromides and other remedies should be used to wipe out the epileptic habit. How much there is in that point I am not able to say. That the hyperesthesia which tends to exist in all recently healed wounds should be kept down to the minimum, and the sensitive cerebral structures blunted as much as possible, seems to me to be a rational idea, and worth a thorough trial.

DR. M. H. RICHARDSON: It seems to me that epilepsy is so serious a disease that almost anything is justifiable, even if it promises nothing more than temporary relief.

In all compound depressed fractures, with or without symptoms, and in simple depressed fractures with symptoms, an operation should be performed at the time, and the fragments should be removed. I believe that there should be no interference in linear fractures or in compound fractures without depression unless there is some evidence of injury to the brain or membrane. Nevertheless, it is to be borne in mind that there may be a comminution of fragments of the inner table with slight depression and very little apparent trouble. I have operated on many cases in which,

though externally there appeared to be little if any comminution, I have found many sharp fragments in direct contact with the dura, and that membrane occasionally lacerated.

I think, from experience gained from my own cases and those of others, that operations for epilepsy promise very little indeed; yet I do not believe that the time has come to abandon all operative measures. All my operations, without exception, have been failures where I have removed depressed fragments after the epileptic habit had become established. In some of them there has been marked displacement of fragments and pressure upon the brain. In none of these cases have I opened the dura mater, however, and I would therefore admit that the operation has not been performed as thoroughly as it might have been. In those cases of others where I have seen radical operations performed, with one or two exceptions, nothing was evident to me at the time to account for the irritation, beyond an adhesion between the dura mater and the brain. In such cases it seems to me absurd to expect much relief except from the operation *per se*, as mentioned by J. William White. Where the operation consists merely of a separation of adhesions between the brain and its membrane, it seems to me that we have no reason to expect much benefit.

The practice of using decalcified bone-plates to assist in closing the skull-opening does not seem to me justified by any experience thus far gained, clinical or experimental. In the surgical application of all animal derivatives we rightly depend upon absorption. Bearing in mind how difficult if not impossible it is to render bone-plates aseptic, their use, it seems to me, is not only of no value, but even dangerous.

As to the matter of drainage, I would agree with Dr. Warren in giving up drainage if he continues to use a strand of gauze in the angle of the wound. It seems to me, however, that that is drainage, and of the very best kind. I, for one, am not willing to give up drainage, except in very rare cases. I believe that this principle has played a most important part in surgery, and that the time has not come when we may safely abandon it. In Dr. Post's case provision was made for the escape of fluids by leaving a gap here and there. That certainly is drainage. I would certainly agree that the use of drainage-tubes should be very limited, and believe that there is nothing better than the gauze (wick) drainage, especially in abdominal surgery. This is quite different from sealing up a wound completely, which seems to me a very questionable procedure, except in rare cases. I have reached this conclusion after considerable experience, more especially in breast extirpations. In many cases the wound became distended with blood-clot which, though aseptic, required several weeks for absorption. Drainage for the first twenty-four hours would have prevented a tedious convalescence.

As to the frequency of traumatic epilepsy, I think it is evidence of some value that we see so few cases of this lamentable condition in comparison with the number of fractures of the skull. From 1880 to the present time there have been numerous cases of fracture of the skull treated at the Massachusetts General Hospital by operation or otherwise. So far as I have been able to ascertain, not one of these cases has ever returned for the treatment of subsequent symptoms. In some, from my personal knowledge, I can say there has been no trouble whatever seen after depression

unrelieved by trephining. It cannot be true that any considerable number of these persons developed epilepsy without seeking relief at the same hospital. Even in cases of depression without symptoms and without operation, I believe the existence of irritation symptoms will rarely be met with.

Nevertheless, as I have already said, I believe the condition frequent enough to make operative interference imperative in *all* depressed fractures, whether simple or compound.

Although the present outlook seems discouraging, I believe in carrying on our work in this direction until we succeed in demonstrating, one way or the other, the value of operative interference in this terrible disease.

DR. G. L. WALTON: The ground seems to have been very thoroughly covered, both from the neurological and surgical points of view. It seems to me that our experience certainly does not authorize great enthusiasm on the subject of secondary operation for traumatic epilepsy, and yet I agree with Dr. Richardson that in such a serious and often hopeless disease even a very small chance is enough to warrant us in attempting an operation wherever we think there is organic local disturbance going on either in the way of depression, cicatrical thickening, or other remains of trauma. I quite agree, however, with Drs. Knapp and Post that we not infrequently find convulsions commencing locally where no organic local irritation exists in the spot naturally suspected. I have seen a case in which convulsions starting accurately in the hand centre were shown by the post-mortem examination to have arisen from an abscess in the temporal lobe; in another case, where epileptic seizures of considerable standing started in the same way, perfect recovery ensued, which would hardly have been probable with an organic source of irritation.

With regard to the head and eyes turning to the opposite side, this seems to be a symptom which is started on very slight provocation, and would least of all lead me to suspect local irritation. I recall a patient who was under my care at one time with headache, loss of vision, and epileptiform attacks. She had one of these attacks in my office, in which the head and eyes turned at the onset violently to one side. The patient seemed rather stupid, indifferent, moved about in rather an automatic manner. I thought the chances were in favor of new growth, and treated her at first with large doses of iodide, and contemplated advising operation if she did not recover, but at the same time recognized the possibility of suppression of menses as cause of the trouble, this symptom having existed for nine months. In point of fact the whole trouble disappeared after re-establishment of the menstrual flow, she became perfectly bright, and was totally unconscious of having been to my office at all. The whole disturbance was therefore reflex, functional.

I remember another case where the principal symptom of tumor was epileptiform attacks in which the head and eyes were turned to the opposite side, together with optic neuritis. The patient refused operation. The tumor was found on post-mortem examination to extend through the motor area of the hand, arm and face, the tip of it only reaching the middle frontal lobe, the posterior part of which is supposed to be, and probably is, the centre of that motion.

It certainly seems as if the habit of epilepsy once set up by traumatic disturbance — whether there be,

as Dr. Putnam suggests, a diffuse sclerosis, or whether there is a process starting from local irritation spreading — whatever may be the cause, the habit once set up, secondary operation offers very little hope; still I should advise operation, as I did in one case of Dr. Richardson's where the convulsions did not come on for about eight years after the injury. Dr. Richardson found a sharp edge of bone pressing in the dura mater. The convulsions disappeared for a time after operation, but recurred in all their severity and frequency; still I should again advise operation in a similar case.

Regarding the consideration of a primary operation with the view of avoiding epilepsy, I think if the case just mentioned had been operated upon immediately after the accident, the epilepsy would probably have been averted, because I cannot believe there was in that case a diffuse sclerosis of the brain or any general injury of the brain. It seems rather that the attacks persisted because the habit had been established to such a degree it could not be averted by removing the original source of irritation.

I am a little sceptical about this diffuse sclerosis playing a very important part, otherwise why should we not more frequently see epilepsy set up by general blows, and falls on the head, unaccompanied by fracture?

In regard to the primary operation, I should not agree with Dr. Agnew that every case of fracture should be operated on, and I am not sure I should with Dr. Warren that every case with depression should be operated on. Of course, in every case of compound fracture I should advise operation, and in every case of punctured wound, and in every case where there is marked depression or depression with very great angle, even if the skin is not broken, or in every case even with moderate depression where there are marked cerebral symptoms.

With regard to decalcified bone I have, perhaps, no right to speak, not having any surgical experience excepting through observation, but I quite agree with Dr. Warren regarding the harmlessness of leaving the opening free, and I see nothing to be gained by inserting decalcified bone, only to be absorbed, and meanwhile, perhaps, to act as a source of irritation.

The case upon whom Dr. Homans operated by my advice last year for hemorrhage produced by contrecoup, experiences no inconvenience whatever from the large cavity which was necessary to the removal of the clot.

DR. W. N. BULLARD: I believe the most important point as to the cure of epilepsy is that the operation should be as early as possible. There is no question about the existence of an epileptic habit. Any one who has any experience of epilepsy knows this. A patient after one attack of epilepsy is much more liable to have another; and after he has had two, the attacks are liable to come with more and more frequency. For some reason the different centres become more irritable by each attack. For this reason I think it is advisable that operation should be performed for epilepsy at the earliest possible period. Of course, in those cases where operations are performed before epilepsy occurs, we have at present no statistics that would enable us to determine their value, because we have no statistics at present to determine how frequently epilepsy occurs after different forms of head injury.

That certain severe injuries, such as compound depressed fracture, should be trephined, I think there can be very little doubt. That every fracture should be trephined where there are no symptoms of local irritation is much more doubtful, and I should think that it was hardly wise to trephine in cases of simple fracture, or in cases where it seemed probable that only the outer table was injured unless with some very definite cause.

Of the traumatic cases of epilepsy which I have seen, a very large proportion have been in persons in whom the injury had existed some years, and I am inclined to think for that reason that in many cases the epilepsy comes on much later than is generally supposed; that is, some exciting cause, perhaps a very slight fall, not injuring the head, or some mental excitement, or some other cause acts at a much later period to produce an epilepsy. Of course, this is simply a matter of theory, not at present susceptible of proof; but the fact that so many cases come late would seem to be in support of it.

In regard to the treatment of epileptic cases the one important thing, in my opinion, is the use of the bromide after the operation. At least two of my cases which have been trephined have had epileptic attacks come on within five days after the operation, apparently simply from the fact that the bromide had been dropped. In one case it had been entirely omitted from the day of the operation. In the second case the bromide was given, but had been omitted two days previous to the attack. After the attack it was resumed, and for three months afterwards there was only one slight attack, which occurred again after omission of the bromide, showing that the bromide evidently had considerable influence.

As to the question of the occurrence of diffuse lesions with localized symptoms of epilepsy, I think there can be no doubt. I have seen several cases in which I have every reason to believe the lesion was diffuse, and yet localized epilepsy occurred.

As to the thickening of the dura after trephining, I have seen it much thickened, and after removing the thickened dura the patient was much better for a time.

I cannot agree with those who think that atrophy of the brain in children is always diffuse. It seems to me there are many cases in which it is not diffuse, but distinctly localized, and many such cases have been published. There are many cases in which the atrophy is diffuse.

As to the replacement of buttons after trephining, I think, as a rule, it is better to leave the button out. In one of my cases it was replaced, and the autopsy sometime later showed that it was perfectly solid, and the lower surface and edges smooth, so that there was no objection on the ground of any roughened edges to replacing it, and it completely filled the trephine hole.

DR. J. A. JEFFRIES: This whole question is one that must be settled by experience. We have started to do operations. They will be continued until the results are determined. So far, they do not seem satisfactory. I have seen a good many cases of traumatic epilepsy, but I have never been able to advise an operation yet. It seems to me we leave about the condition we operate to prevent in the shape of adhesions, irregularities, especially if we put back the button. If the operation effects a cure, it would almost seem that the scars are not the cause of the epilepsy.

DR. R. H. FITZ: recalled the recent discussion of this subject in Washington, in which ground had been taken

similar to that presented by the readers and speakers this evening.

It seemed to him that sufficient evidence had been accumulated in different parts of the world to warrant the opinion that the operation of trephining for traumatic epilepsy was no longer justifiable (admirable is, perhaps, a preferable term). It is almost universally agreed that no permanent benefit follows, and, as a rule, but little immediate relief.

It is not even certain that the latter is a result of the trephining. In Washington, Dr. H. C. Wood had stated his knowledge of the production of temporary relief from mock and trivial operations, and urged that these should first be tried before so serious an operation as trephining should be undertaken.

Great weight should be attached to the view expressed by Drs. Knapp and Putnam as to the probable, general and remote lesions of the nervous system in traumatic epilepsy. The discovery of thickened membranes, adhesions and cystic edema at the seat of an operation is no satisfactory evidence of the local origin of the disease, much less of the need of the operation. He knew that sufficient discrimination at this time was not always exercised between what was abnormal and what was pathological. A sclerosis of the diploë, an adherent or thickened dura, bone-plates in this membrane, vascular threads between the dura and pia, thickening, opacity and edema of the latter were of such frequent occurrence in the absence of epileptic symptoms that he could attach little or no etiological importance to their presence in epileptics. Even the concurrence of a depression in the outer table at a seat of injury and epilepsy was no evidence that a subjacent intracranial lesion was to be found. A fact well illustrated by Dr. Post's specimen.

Recognizing, like his surgical colleagues, that traumatic epilepsy was almost hopeless, he could not agree with them that trephining should, therefore, be advised, even in cases of depression. Certainly not while mock or trivial operations may be considered as capable of giving equally satisfactory therapeutic results, and the graver operation is so rarely followed by any considerable or prolonged benefit.

DR. P. C. KNAPP: Dr. Bullard has just told me that he saw the first patient whose case I reported, after she left the hospital, and that she still had a continuance of the fits.

Dr. Putnam speaks about the cases treated on the preventive method. I think that the number of cases, where trephining has been done with the aim of preventing epilepsy and not with the aim of relieving some cerebral symptoms present at the time, are as yet extremely few. The suggestion of trephining, for instance, in simple linear fracture, was made only a year ago by Mr. Horsley, and there are very few cases, if any, that have been operated on simply on that basis. Of course, when you get a depressed fracture or compound fracture with cerebral symptoms it is not preventive trephining.

With regard to the adhesions that may sometimes follow, I noted them not long ago in making an autopsy after trephining. It was a case of brain tumor where Dr. Bradford trephined for the relief of pressure, and the adhesions of the membranes about the trephine opening were very great.

The after-treatment by bromide was adopted in both of my cases without any result.

In regard, furthermore, to diffuse lesions, there is

one affection where certainly there are general diffuse lesions and where partial epilepsy is very common, namely, general paralysis, which has hardly been mentioned to-night.

Dr. Walton has stated that secondary operation is practically useless, and Dr. Fitz goes so far as to consider it unjustifiable. I think Dr. Fitz's position is hardly tenable, for it is an undoubted fact, and there are a good many cases now on record where after such operation we get distinct relief from symptoms for two or three years, or longer. Now, considering the very slight risk from trephining, certainly if we can give the patient a prospect of a few months' relief, as in the case reported by Dr. Beach, or of the general improvement in that girl's condition, even with the recurrence of the fits, certainly the operation is perfectly justifiable. I saw a few weeks ago one of the early cases of excision of the cortex for Jacksonian epilepsy, a case reported three years ago at Washington by Dr. Lloyd, where for a number of months the man was entirely free from convulsions. As Horsley said, three years ago, in that time the brain may so far recover itself that it may come out from the state of partial dementia, due to the convulsions, and get into a much more healthy state. Even in the cases that are a failure, strictly speaking, if we can reduce the number and severity of the convulsions, the operation is certainly justifiable.

In the report of his operation, I remember Dr. Beach made a suggestion of preventing possible adhesions between the brain and the membrane, by covering with gold foil. I do not know whether that has ever been carried out. That, certainly, would not be particularly irritating, and would not be absorbed.

DR. J. J. PUTNAM: I think we want more facts rather than opinions in the matter. Dr. Walton thinks Dr. Richardson's case if operated on earlier, would have prevented attacks, but I don't see any ground for saying so. The symptoms were not especially localized with relation to the seat of the injury, I think. It seems to me that would be rather one of the cases I had in mind when I said that the epilepsy might be due to distant or to general and diffuse lesions. I want to say a few words about that. In speaking of diffuse lesions, I said that they were often found later in epileptic brains, although I admit what Dr. Bullard said, namely, that in the case of children the cerebral sclerosis may be more or less localized, as in so-called tuberous sclerosis. What I meant to say was, that the lesion that caused the epilepsy need not be necessarily directly beneath the injured bone. It is very easy to say that the irritation sets up a discharge at a certain point, and that this discharge then spreads out. That this is possible there is no doubt, but we do not really know what may go on before a discharge of a certain centre occurs. That particular discharge may be only the expression or outcome of morbid processes taking place elsewhere. Lesions which contribute to make the whole brain unstable may indirectly cause the epileptic outbreaks, either independently of the special local lesion or in conjunction with it. I understood Dr. Walton to say really the same thing I did in speaking of the cases where epilepsy began with certain symptoms, and yet where no lesion was found at the parts of the brain corresponding to those symptoms.

Dr. Bullard spoke of contributing causes of accidental kind causing epilepsy, which would otherwise remain latent. That is a very important matter, and

that I referred to and would like to dwell on a little more in connection with the case of my patient and Dr. Beach's. The whole thing seems to have been brought back by a fall from a wagon. Up to that time she had been wholly free. Epileptic patients sometimes have their attacks brought on by bright or loud sounds. In a discussion on this subject, in connection with the statistics of the German army, the question of predisposition is dealt with as being very important.

The surgeons and all of us have spoken of the *probable* value of early operations. I do not know that any of us have given sufficient reason for deciding that they are *certainly* of value to the extent often supposed. I think that it is an opinion which we have formed, and which has a certain amount of basis, but does not, perhaps, have such basis as we could wish.

With regard to bone-plates, I have only to say that I took my statements mainly from Ziegler's Anatomy. I did see one case where the bone-plate was a possible cause of epileptic attacks. In general, I agree with what Dr. Fitz said, that they were usually not centres of irritation. That is what I specially called attention to in my paper.

The matter of general paralysis is important, and I referred to it in speaking of the diffuse processes.

As regards advisability of operating in cases of traumatic epilepsy, if we understand what it is done for and do not deceive ourselves and the patient, it is justifiable to do it for the sake of gaining a little time, just as we might operate for cancer under similar circumstances.

We have all of us seen patients who would give anything for a year's release from such symptoms as epilepsy.

MYXO-SARCOMA OF THE THIGH.

DR. J. C. WARREN: I have here a large tumor of the lower part of the femur of a woman of seventy, whose thigh I amputated on Saturday.

The history of the case is briefly this, that some ten years ago I removed a myxoma from the inner condyle of the left femur, which was followed in the course of a year by recurrence of the tumor. I have seen the patient from time to time, and owing to her age and to the extensive involvement of her thigh, I advised her not to have anything done. I have not seen her for a year or two. She appeared at the hospital a week ago with an enormous tumor of the lower part of the femur, and was very anxious to have it operated upon. I was struck by her general good condition and the fact that the tumor was still localized, although it had existed so long a time and was of so large size. With the understanding that it was a very serious operation, but that we were justified in operating to relieve the great pain from which she was suffering, I operated on Saturday. The patient is still alive, and although she has suffered a good deal from shock, still she is doing well to-day.

It is a large myxo-sarcoma of the soft parts or parts involving the periosteum. It does not involve the knee-joint. The patient was able to walk about.

I think I advised her for the best. She has had several years of comparative health so that she could take care of herself and get about. Now that she is completely disabled and suffering and nobody to look after her, it seemed advisable to interfere.⁴

⁴ Three weeks later the patient was doing well and the wound had healed except at the point of insertion of drainage-gauze.

NEW YORK NEUROLOGICAL SOCIETY.

MEETING of December 1, 1891, the President, Dr. L. C. GRAY in the chair.

DR. CHARLES A. POWERS read a paper with this title:

RESECTION OF POSTERIOR BRANCHES OF UPPER THREE CERVICAL NERVES FOR SPASMODIC TORTICOLLIS, WITH REPORT OF CASE.

In February of the present year, the patient, a man thirty-seven years of age, was sent to the speaker for an opinion regarding a spasmodic affection of the neck from which he was suffering. There was no history of syphilis or other constitutional disease. He had been from boyhood exceedingly nervous and restless, starting violently when suddenly surprised, trembling at the slightest injury or fear of danger. His father had always manifested the same nervous conditions in a marked degree. The patient had rather a senile look, stooping and throwing the head well forward. When left to itself the head was spasmodically rotated to the right to its fullest extent. The patient could carry it back by pressing the chin over with the hand, but when the restraining force was removed it was instantly jerked back to its rotated condition. These spasms were constant during the day, and much worse when the patient was fatigued, irritated, surprised or among strangers. The right hand was constantly upon the chin, and the patient was unable to use it in work or even at table. The right shoulder was not elevated, there was no spasm of the muscles of the left side and the right trapezius, sternomastoid and scalenus anticus seemed free from implication. The patient's neck was large, thick and short; it seemed somewhat fuller on the right side, posteriorly, than on the left. The spasmodic movement seemed to be a rotation of the occiput upon the atlas; when it took place an increased fulness could be felt in the region just below the occiput and covered by the trapezius, although no contraction could be felt in that muscle. After very careful examination the affection was considered to be confined to the posterior rotators, and division or resection of the nerves supplying them was recommended.

The speaker, after familiarizing himself with the anatomy of the parts, by dissection on the cadaver, proceeded to operate. The occipital region was shaved and the parts prepared in the usual way. The anesthetic was given, and the patient placed flatly upon his abdomen, the head projecting over the end of the table, and so held that the external occipital protuberance was in a straight line with the vertebral spinous processes. A three-inch transverse incision was made at the back of the neck, beginning at the median line one and one-quarter inches below the external occipital protuberance and running forward. This was sufficiently enlarged until it measured four and a quarter inches in length. After some difficulty the occipitalis major nerve was found at the upper part of the complexus outside of the intra-muscular aponeurosis of this muscle. The complexus was divided and the nerve followed back to the posterior branch of the second cervical. The inferior oblique muscle was then found, passing from the tip of the transverse process of the atlas to the spinous process of the axis. The nerve was followed back to its exit from the spinal canal. Following down beneath the complexus the external branch of the posterior division of the third cervical nerve was found. This was traced back to

the bifurcation of the main trunk. One had at command, then, the nerve-supply to the inferior oblique, the rectus capitis posterior major and the splenius, the three posterior rotators, the first being supplied by the first and second cervical, the rectus by the suboccipital from the first cervical, and the splenius by the second and third cervical. Each nerve was followed well back to the spine, and from one-half to three-quarters of an inch excised from each of the three. Buried muscular sutures were inserted, a drainage-tube laid to the bottom of the wound, and the skin sown up. A large antiseptic dressing was applied, and the head fixed in moderate extension by plaster.

On coming out of the anesthetic the patient had no spasm of the neck; the head was in the median line, and remained there until the final removal of the dressings. The wound healed per primam throughout. The tube was removed on the fifth day, and all dressings were taken off at the end of ten days. At that time there were a few slight spasms, but they did not persist. Directions were given regarding massage and the like, but these were disregarded, and the head gradually assumed a position of contraction, with the face drawn to the right. In spite of the patient's present contracted wry-neck he expressed himself as feeling that his condition was vastly better than it was before the operation.

Appropriate after-treatment, by confinement of the head, massage, etc., should receive careful attention. The speaker could but think that if such measures had been conscientiously carried out in the present case, deformity would have been much less.

DR. R. W. AMIDON thought Dr. Powers had been too modest, in that he had not called attention to the marked improvement in the patient's right arm. Before the operation this had been practically powerless, while now its functions were restored. The position of the head was now similar to that before the operation, but the spasm was now tonic instead of clonic, and therefore much more endurable. There was now no elevation of the chin which was conclusive proof that none of the muscles originating or inserted in the occipital bone were now implicated. The elevation of the right shoulder was now much more marked, and there was no doubt that the levator anguli scapulae entered largely into the production of the deformity.

DR. C. L. DANA thought the muscles of the right side, which were cut, had possibly entered into the production of spasm, but that the nerve force was now distributed through fewer channels, and perhaps this was the reason that the spasm was now tonic. The question was, at any rate, of extreme interest, because heretofore there had been much scepticism as to the value of operation for wry-neck. He thought that the experience of American observers was that operation on the spinal accessory had been uniformly fruitless, but the relief obtained, where the upper cervical nerves were involved, had given a more favorable showing. With better technique perhaps more favorable results would come in the case of the spinal accessory. He did not doubt but that the condition under consideration was the result of a central nervous lesion. Why surgical treatment should cure he did not know unless it was the result of the operation, *per se*.

DR. M. A. STARR had seen these cases treated by division of the spinal accessory. No improvement had followed. He had therefore hesitated to recom-

mend such procedure. He thought it had yet to be demonstrated that the condition was one of cerebral origin, as there was nothing analogous to wry-neck in the form of cerebral spasm of any other muscle. A patient had come to him last February with an extremely pronounced case of wry-neck. This patient had noticed that pressure on the right side of the occiput, high up, would relieve the spasm. An apparatus was accordingly constructed which, being constantly worn, enabled him at the onset of the spasm to bring the necessary pressure to the required spot by means of a system of levers worked by his arm. The speaker had that day seen the patient, and had found him apparently perfectly cured and able to leave off the apparatus.

DR. W. M. LESZINSKY thought that there was a lack of such pathological knowledge of the disease as would indicate that there existed a central lesion. It was remarkable that so few microscopical examinations had been so far made of nerves which had been resected. In the present case they had not been offered any explanation as to the cause of the arm symptom, and whether it was supposed to have borne any relation to the spasm in the neck. He had been interested in a few cases of spasmodic wry-neck, and felt confident that the hypodermic injection of atropine had helped them. He had reported such a case in which the spinal accessory was implicated, and he had felt that the benefit done was the result of the atropine. He thought that this measure should be energetically tried as part of a treatment by drugs before surgery was resorted to.

DR. J. M. MORTON cited the history of a patient who had come to him with a well-marked case of spasmodic wry-neck of long standing. Every effort had been made therapeutically. He had tried suspension. The seances had numbered about five, each lasting about five or six minutes, the patient's toes being just free of or barely touching the floor. Improvement had been prompt and had continued to a cure which had been maintained up to the last report.

THE PRESIDENT had never seen any good results from operative work in these cases. While out of a large number operated upon for him by different surgeons, temporary improvement had taken place in some, relapse had ultimately occurred. He had obtained more satisfactory results by deep injections of atropine than from any other form of treatment, though he had found the internal administration of belladonna effective. As to the permanency of the atropine benefit he could not speak, the patient having passed from observation. Temporary results were worthless for deduction and relapses were probable at any time.

ALLEGED CEREBRAL TUMOR.

DR. LESZINSKY showed a patient whom he had presented to the Society three years ago; at that time the diagnosis was made of cerebral tumor. The symptoms had then been frontal headache, vomiting and double optic neuritis. Now this man was in perfect health, and since treatment had never lost a day's work from illness. There was atrophy in both optic nerves. Vision was in one eye, $\frac{1}{2}$; in the other, $\frac{1}{2}$. There was no disturbance in the color field. The treatment during the acute stage had been by large doses of iodide of potassium with leaches and cathartics when the inflammation was excessive.

THE BOSTON

MEDICAL AND SURGICAL JOURNAL.

THURSDAY, JANUARY 7, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DANRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE BACILLUS COLI COMMUNIS.

IN a presidential address before the Medical and Chirurgical Faculty of Maryland,¹ on November 17th, DR. W. H. Welch gave an outline of his recent study of this bacillus. The differences between the bacillus coli communis and the typhoid bacillus are briefly as follows:

The typhoid bacillus is actively motile, the colon bacillus only feebly motile; the typhoid bacillus never coagulates milk, the colon bacillus coagulates it in two to seven days; the typhoid bacillus does not cause fermentation of lactose, or if at all, only in very feeble degree, while the colon bacillus actively ferments lactose. There are also differences in the appearances of the growth of the two bacilli on gelatin, agar and potato, but these are less precise and constant than the points mentioned.

The author's investigations have proved that lesions of the mucous membrane of the intestine open the way for the invasion of the colon bacillus into the blood and lymphatic vessels, and thence into various organs and parts of the body. They were found with especial frequency in the lungs and kidneys, but often also in the liver, mesenteric glands, and spleen. In a number of cases colon bacilli were demonstrated by culture methods in various organs of the body without any noteworthy lesions of the organs containing them or any lesion that could reasonably be referred to their presence. There is, therefore, no evidence that in these cases the bacilli do any harm, although it cannot be positively stated that their presence is innocuous. It is well known that human blood-serum outside of the body exerts a powerful germicidal influence upon the colon bacillus.

The author has suspected that the colon bacillus may be the cause of lobular pneumonia, as in several cases this organism has been found in large number and in pure culture in congested, edematous, and inflamed areas in the lungs. It has also been frequently associated with fatty degeneration of the kidneys, but neither in this nor in the pulmonary affection is there

¹ Medical News, December 12, 1891.

any conclusive evidence that the presence of the bacilli has done the harm.

In cases of peritonitis due to perforation of the intestine the colon bacillus is usually found, but not always, in large number in the exudate, sometimes in pure culture. It is a mistake, however, to say, as Malvoz has recently done, that all cases of peritonitis due to intestinal lesion are referable to the colon bacillus. Often enough in this class of cases the staphylococcus pyogenes aureus or the streptococcus pyogenes is present—it may be predominantly so—in the peritoneum.

Typhoid ulceration of the intestine opens the way for the invasion of the colon bacillus, which may be found in different organs, mixed with the typhoid bacillus. On account of the resemblance between these two species of bacilli a mistake has probably often been made in identifying the colon with the typhoid bacillus. The preservation of all its properties in these cases shows that the colon bacillus is not changed into the typhoid bacillus when it invades the organs in typhoid fever.

Only in two cases has the author found the colon bacillus in organs outside of the intestine without any demonstrated lesion of the alimentary canal. Although careful search was made, it is not improbable that some lesion was present.

REPORT OF THE SURGEON-GENERAL OF THE ARMY FOR THE YEAR ENDING JUNE 30, 1891.

THE army is coming nearer to our daily lives in the effort of the General Government to bring the regular army and the militia into closer relationship. A community of interest between the citizen soldier and the regular is more and more apparent. There has always been a community of interest between the civilian physician and his brother in the army. Educated in the same schools and trained in the same hospitals, the fact that one wears a uniform while on duty does not separate them any more than the same distance would do were they both civilians.

The variety of hygienic and scientific problems that the military surgeon is engaged upon at the present time is as great as that which interests his military brother of the line or his medical brother in civil life, and the Surgeon-General's Report gives some idea of the multifarious duties and almost universal knowledge required of the army surgeon.

The closer relationship which is being fostered between the army and the State Militia is well illustrated in its medical aspects. During the year included in the report, medical officers accompanied detachments of United States troops which were encamped with the militia of Pennsylvania, Iowa and Michigan. The extracts from their reports are extremely instructive as army surgeons prove keen critics of the shortcomings of their militia brethren, while very ready to recognize merit. It is evident that the vicious custom

of allowing colonels to appoint their own surgeons without examination is still preserved in some States. This custom was the source of great evil in the early days of the Rebellion, and ought not to be tolerated in any force which is liable to be called upon for active service. The regular medical officers used their opportunities to impress upon the medical officers of the National Guard, with whom they were brought in contact, the importance of their position and the fact that their duties have a much wider range than mere prescribing for such individual disorders as may by chance present themselves. The work of the hospital corps and company bearers was demonstrated. In general, it may be said that the presence of an army surgeon at a State encampment may evidently be a powerful stimulant, not merely to the medical force present, but more or less directly to the entire militia force of the State.

Some of the most interesting material in the report refers to the hospital corps, which had an opportunity to demonstrate its value in active service in the Sioux Campaign. Of it the Surgeon-General writes: "On the battlefield at the action on Wounded Knee Creek two of its members rescued a wounded officer from extreme peril under circumstances which fully entitled them to the certificate of merit which they received as their reward, while the services of the remainder rendered were so orderly and well regulated that not only our own wounded men, but wounded Indians were, with great promptness and dispatch, removed and cared for in the field hospitals which were extemporized for their benefit."

These wounded Indians, by the way, were not exactly comfortable patients. The simplest handling was met at first with suspicion and resistance. Their wounds were mostly severe and all capital operations were refused, notwithstanding explanations by missionaries, interpreters and friends. In cases of extensive injuries to the large bones or joints, septic fever came sooner or later and finally death.

The many references to the hospital corps by different officers under different headings show the great interest felt in this organization and the enthusiastic work which is steadily applied to it. To bring it nearer perfection, companies of instruction are in process of organization at three different forts. Each company is to be fully instructed in first aid to the wounded, management of field hospitals, cookery and such other matters as are necessary to secure the highest state of efficiency for field service.

Col. Joseph R. Smith, medical director of the department of Arizona, suggests that drunkards should be at once dishonorably discharged from the hospital corps and the attempt to discipline them abandoned. This suggestion, which will meet the hearty approval of hospital executive officers everywhere, is in accord with the system of summarily discharging men found, on trial, to be worthless or incorrigible; a system recently adopted in the army and which has proved of great benefit to the service.

Another scheme to prevent the enlistment of men of bad character who have previously deserted or been discharged, is worthy of much greater space than is devoted to it in the report. This is the record on cards of the personal markings of every recruit, that is, the congenital marks, scars, tatooings and other peculiarities. This system differs from the Bertillon system of identifying criminals in that no measurements are used, the record being confined to the surface markings, which are recorded on uniform charts furnished for the purpose. These charts or cards are filed in Washington, where they are kept for consultation. Although this system of records was only begun in April, 1889, thirty-four recruits have since then been recognized as deserters, twenty-six as ex-convicts and sixteen as frauds of a minor grade. It is expected that in process of time this system will be so perfect that it will be impossible for so-called "repeaters" to escape detection.

The "repeater" of to-day was the "bounty-jumper" of the war; and this elaborate system of identification recalls the act of a Boston physician, who, while acting in the capacity of an examiner of recruits, marked one man whom he recognized, with a D with nitrate of silver, in order to attract the attention of any other examiner, and prevent further fraud on the part of the recruit. This act of patriotic intention was the basis of a suit in which the physician was charged with assault or some similar infringement of the personal rights of the bounty-jumper whose trade was temporarily spoiled by the deserter's mark; and another Boston physician, while on the stand as a witness for the defence, boldly marked his bared forearm with silver nitrate to demonstrate to the jury the slight character of the offence.

It is perhaps an open question whether any system of identification would be adequate to the prevention of fraud when recruiting was going on as rapidly as during the Rebellion. Even now the proper indexing of this card-catalogue of humanity must be quite a problem, though no difficulty is mentioned in the report.

There are many other matters of interest in the report; but enough has been said to show that an army surgeon has many interests outside of the study of individual cases of disease and injury.

THE ASSOCIATION OF MILITARY SURGEONS OF THE NATIONAL GUARD.

A PRELIMINARY notice of the second annual meeting of the Association of Military Surgeons of the National Guard of the United States has already been sent out. The meeting is to take place in St. Louis on April 19, 20 and 21, 1892. The object of this Association, as given in the preamble to its constitution, is to promote and better the science of military surgery, and at the forthcoming meeting "all matters pertaining to the health, usefulness and welfare of the civilian soldiers will receive attention." The after-

noon of one day will be set apart for an object-lesson from the "Manual of Drill," by hospital corps of the United States Army, detailed for this purpose. The announcement speaks of this drill as "a very important, as well as instructive, feature of this session." It is but another means of affiliating the medical corps of the army and of the National Guard.

If this Association can accomplish the objects for which it is established, it deserves the support, not of militia surgeons alone, but of the profession at large. The army medical standard, as well as that of other government establishments, has always been particularly high, and its influence has been to raise the grade of professional attainments in a country where there has been an unfortunate tendency to lower the standard. On the other hand, in the militia in general the standard has been low. This is a sweeping statement which has numerous brilliant exceptions. If this Association will change all this, and raise the militia standard until a commission is in all the States an evidence of professional attainments, it will do indirectly for the benefit of the profession at large nearly as much as it accomplishes for the militia.

MEDICAL NOTES.

A NEW HOSPITAL IN CALIFORNIA.—By the will of the late Mrs. Catherine Garcelon, of Oakland, Cal., the sum of about \$600,000 is bequeathed to found a hospital in Oakland. Bowdoin College is to receive about \$400,000.

INFLUENZA.—During the past week, the epidemic of influenza has shown no signs of abating, either in this country or in Europe. Beside the countries of northern Europe, the northern part of Italy is suffering severely, especially the cities of Milan and Genoa. It is announced by cable from Berlin that the method of propagation of the specific organism of the disease has been discovered.

THE CONTAGIOUSNESS OF INFLUENZA.—It is reported by cable that the health authorities of Dover, in England, have accepted the contagiousness of influenza as a fact, and have arrested and fined a number of persons who are suffering from the disease, for frequenting public places while suffering from a contagious disease, in violation of law.

RELIEF FOR RUSSIA.—The Governor of Massachusetts has issued an official appeal for contributions in aid of the sufferers from the famine in Russia, in which he says, that official statements show that there is a deficiency of seventy-five million bushels in the grain needed up to the time of the next harvest. Unless help comes speedily, extreme suffering and many deaths by starvation must ensue. The Federal Government and three States have already issued appeals. The Governor has appointed as a committee to take charge of the contributions, Rt. Rev. Phillips Brooks, Rev. Edward Everett Hale, O. W. Peabody, William Lloyd Garrison and Josiah Quincy.

CHOLERA AMONG SHARKS.—A report comes from Bombay that an epidemic of cholera has broken out among shoals of sharks that infest the Indian Ocean. The bodies of seventeen British seamen, who had died of cholera in the harbor of Bombay, on the hospital ship, were sewn up in canvas, taken out to sea, and "buried." It is believed that a shoal of sharks feasted upon the remains of these victims of cholera, and thus became infected.

NEW ENGLAND.

THE MORTALITY OF BOSTON was higher last week than it has been since January, 1890. The number of deaths was 313, making a death-rate of 36 per thousand. Among the causes of death were pneumonia 85, consumption 36, bronchitis 30. Thirty-three were stated as due to influenza, of which 24 were complicated with some other disease. The number of persons who were over sixty years of age was 109.

BOSTON CITY HOSPITAL.—The following order was recently passed by the Boston Common Council: "That the Board of Trustees of the City Hospital, through His Honor the Mayor, be requested to consider the advisability of establishing a branch of the City Hospital in Brighton District and also one in East Boston or Charlestown, and report to the next City Council the result of their deliberation."

THE MASSACHUSETTS SCHOOL FOR IDIOTIC AND FEEBLE-MINDED YOUTH, which for over forty years has been situated in South Boston, has been lately transferred to its very convenient new buildings in Waltham, near the Clematis Brook station of the Fitchburg Railroad. The school is the oldest of its kind in America. It was opened in 1848 with three private pupils and ten State charges. During the past year it cared for about three hundred, a large number of whom were beneficiaries of the State.

NEW YORK.

A NEW SITE FOR COLUMBIA COLLEGE.—As Columbia College is considerably cramped for room in its present location, it is probable that another site will be selected for it, and a committee has been authorized by the trustees to secure from the New York Hospital a six months' option on a portion of land now occupied by the Bloomingdale Asylum, the department for the insane of the hospital, which is shortly to be removed to White Plains.

THE BOARD OF HEALTH.—The Board of Estimate and Apportionment has allowed the sum of \$435,138 for the expenses of the Board of Health during the coming year; which is about \$15,000 more than was allowed last year. Among the items is \$30,000 for enlarging the Reception Hospital at the foot of East 16th Street. The Commissioners of Charities and Correction asked for an appropriation of \$2,877,245, but the amount allowed was \$2,171,383.

THE PRESBYTERIAN HOSPITAL.—The new buildings of the Presbyterian Hospital were formally opened with a reception to invited guests, on the 19th

of December. They are eight in number, some of them standing on the site of the pavilions destroyed by fire in December, 1889, and are built of brick, trimmed with brown-stone, terra-cotta, and blue-stone. They include a medical pavilion, two surgical pavilions, an isolated pavilion for infectious diseases, a dispensary and an operating theatre, and the entire cost has been over \$875,000. The two principal pavilions, which are five stories in height, have been built with flat roofs, in order to provide a roof-garden and solarium for the patients.

Miscellany.

THE NON-CONTAGIOUSNESS OF LEPROSY.

At a meeting of the New York County Medical Association held December 21st, Dr. L. Duncan Bulkley read a paper on "The Non-Contagiousness of Leprosy," in which he gave the following as his conclusions:

- (1) Leprosy is not in any proper sense of the word a contagious disease.
- (2) There is not the slightest warrant for public alarm concerning cases of leprosy.
- (3) It is not due to climatic or race conditions.
- (4) It originates from a bacillus.
- (5) There is reason to believe that under certain conditions it can be inoculated.
- (6) There is considerable ground for the opinion that it is frequently caused by food and especially fish.
- (7) Heredity is a possible factor in its causation.
- (8) There is far greater warrant for the seclusion and regulation of syphilis and tuberculosis than of leprosy.

NEW REGULATIONS OF THE NEW YORK COMMISSION IN LUNACY.

At a meeting of the State Commission in Lunacy held at Albany, December 5th, a number of regulations were adopted, among which are the following:

That no license will hereafter be granted to operate and maintain an institution for the care, custody or treatment of the insane, unless such institution shall be constantly in charge of a well educated resident physician, who shall possess the following qualifications: He must be a graduate of a legally incorporated medical college, and must have had at least five years' actual experience in an institution for the care and treatment of the insane. In existing institutions this order will in all future appointments be held to apply.

That hereafter the approval of the Commission in writing will be required upon the appointment of all assistant physicians in licensed institutions for the care, custody or treatment of the insane. In existing institutions this order will in all future appointments be held to apply.

That no voluntary patient shall be admitted to a licensed institution for the care, custody or treatment of the insane permitted to receive voluntary as well as committed patients, whose mind is so impaired as to render him incapable of forming a rational judgment as to the disposition of his person, or whose will is so weak as to render him incapable of resisting undue influence. (A special form of application, to be accom-

panied by the certificates of two suitable witnesses, is to be signed by all voluntary patients seeking admission to such institutions.)

OBITUARY.—BUCKMINSTER BROWN, M.D.

In the death of Dr. Buckminster Brown, this community has lost a man of more than ordinary professional achievement, who held for many years a position of well-earned distinction. To have attained to prominence in the profession of medicine, it is in itself a success, but to have succeeded in the race of life, hampered by physical infirmity which would have hindered the work of any one except a person of unusual character, is indicative of great determination, high purpose, and unusual energy of spirit.

Dr. Brown was born in Boston, July 13, 1819. With excellent educational advantages here and abroad, inheriting a place, as it were, in the profession, he enlarged his opportunities and made for himself a name which was known beyond the confines of the community in which he lived. His life and career were necessarily very much apart from the ordinary run of the bustling life of an active city, and it is chiefly to men of his specialty that the true value of his work is fully known. Supplementing his father's initial efforts, Dr. Buckminster Brown was the first to develop in America orthopedic surgery as a specialty; and by him the methods in vogue in England at that time, were carried out with a completeness, a thoroughness, a mastery of detail, a persistency of purpose, which deserved and won unusual success.

At a time when many men were diverted to more brilliant fields of surgery, Dr. Brown persistently carried out the painstaking and thorough methods needed in curing long-continued chronic affections and no case that he attempted suffered from the lack of great perseverance on the part of the attending surgeon.

In his later years his activity was limited by increasing infirmities, but he won, in what may be considered his old age, at a time when most are glad to lay down responsible effort, a triumph which adds reputation not only to his own name but to that of his city, in a cure of a case of double congenital dislocation of the hip-joint, by long and persistent treatment by traction and recumbency. This case demanded for its success not only unusual powers as a practitioner, (and these Dr. Brown possessed to a more than ordinary extent,) but also great persistency, originality of thought, and an amount of courage of conviction which is not ordinarily demanded in everyday surgery. The case is a unique one, and in all probability will remain for some time one to be quoted and admired as a model and an example of success by an unusual method of treatment of a hitherto incurable affection.

Dr. Brown's contributions to medical literature were always carefully considered. He was not a voluminous writer, and the list of his writings is not a large one; but whatever was written was most carefully and thoroughly done, and in a careful, scholarly spirit. He represented the English school of orthopedic surgery, and the excellent qualities of that school at its most active and productive period. Although he did not care to consider himself a specialist, yet his work was almost entirely special, and his career emphasizes the benefit of specialization and special work. In fact, he was one of the first of specialists in point of time; but his attention was also called to work outside of his specialty; and a case which illustrates this is the cure of an iliac aneurism by pressure which was used while the patient walked about. The result was demonstrated by an autopsy which occurred several years later, and was reported by Dr. Beach of this city.¹ The case is one that deserves especial mention in the history of the treatment of aneurism.

Besides his remarkable case of congenital dislocation, Dr. Brown's most brilliant success was in the treatment of club-foot, which, considering the methods which were then in vogue, is a monument to thoroughness, persistency and faithfulness.

Valuable articles were also written by Dr. Brown, on the correction of the deformity and contraction of the hip-joint and extension in the treatment of diseased vertebrae.² Whatever Dr. Brown wrote is of value, either as evidence of current surgical practice of the time or as of permanent interest in the annals of orthopedic surgery, a specialty he did so much to advance.

THERAPEUTIC NOTES.

THE TREATMENT OF PNEUMONIA.³—The *Séminaire Médical* summarizes the modes of treatment of several physicians of Paris. Professor Bouchard considers acute pneumonia as a local malady, caused by a micro-organism whose seat is in the pulmonary tissue. As to treatment, he has not yet commenced his researches, but he hopes to be able to find a specific for the pneumococcus. Professor Cornil said that as *chef de clinique* of Bouillaud, he gave two bleedings at the beginning of the malady, but the result was neither less or more successful than now. He gave as his own treatment scarifications followed by a blister and the administration of an alcoholic potion, with Dover's powder. M. Chauvillard was convinced that no remedy has been discovered which would neutralize the toxic of the pneumococcus nor abridge the vitality of the pathogenic agent. M. Dujardin thought that the state of the heart in pneumonia was the chief consideration, consequently he treats the disease, especially in alcoholic subjects, with injections of *cafféine*. He prefers the preparations of kola, or that of coffee or tea to those of alcohol. To calm the nervous manifestations he prescribes chloral, but he never gives opium. As to blisters, he employs them only when the fever has abated. Professor Peter treats the robust by scarifications *loci dolentis*, and the weak and aged by alcoholic stimulants. M. Bucquoy considered sulphate of quinine as very useful in most cases, and prescribed alcohol in pneumonia of the summit and in the aged. M. Muselier follows the same method, but rejects completely blisters. Professor Jacoud treats specially symptoms. Dr. Huchard recommends injections of caffeine combined with ether, from four to eight injections daily, representing eight grains of caffeine, as he considers the danger to be at the heart.

RECORD OF MORTALITY
FOR THE WEEK ENDING SATURDAY, DECEMBER 19, 1891.

CITIES.	Estimated population for 1890.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Acute lung diseases.	Scarlet fever.	Typhoid fever.	Diphtheria and croup.

Deaths reported 3810; under five years of age, 1266; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas, and fevers) 605, acute lung diseases 736, consumption 372, diphtheria and croup 283, scarlet fever 92, typhoid fever 71, diarrhoeal diseases 71, measles 21, whooping-cough 18, cerebro-spinal meningitis 17, erysipelas 14, malarial fever 8.

From diarrhoeal diseases Chicago 18, New York 16, Baltimore and Charleston 4 each, Philadelphia, Pittsburgh and Washington 2 each, Brooklyn, Boston, New Haven, and Lowell 2 each, Milwaukee, Lowell, Cambridge, Springfield and Newton 1 each. From measles New York 17, Brooklyn 2, Cincinnati and Pittsburgh 1 each. From whooping-cough New York 4, Philadelphia 3, Boston, Pittsburgh and Washington 2 each, Brooklyn, Baltimore, Milwaukee, Nashville and Lowell 1 each. From cerebro-spinal meningitis New York 4, Chicago and Worcester 3 each, Milwaukee 2, Philadelphia, Brooklyn, Washington, Nashville and Chelsea 1 each. From erysipelas New York and Chicago 4 each, Pittsburgh 2, Brooklyn, Boston, Milwaukee and Cambridge 1 each. From malarial fever New York and Brooklyn 3 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,405,108, for the week ending December 12th, the death-rate was 19.8. Deaths reported 3,580: acute diseases of the respiratory organs (London) 348, whooping-cough 116, measles 92, fever 55, diphtheria 49, diarrhoea 48, scarlet fever 42.

The death-rates ranged from 12.4 in Norwich to 45.1 in Plymouth, Birmingham 18.8, Bradford 17.5, Hull 13.5, Leeds 20.6, Liverpool 25.0, London 18.1, Manchester 19.5, Nottingham 21.6, Sheffield 18.1.

In Edinburgh 45.4, Glasgow 26.3, Dublin 25.2.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 26, 1891, TO JANUARY 1, 1892.

CAPTAIN SAMUEL A. ROBINSON, assistant surgeon, U. S. A., granted leave of absence for twenty days to take effect on or about January 2, 1892.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—The annual meeting of the Society will be held on Monday, January 11, 1892, at the Medical Library, 19 Boylston Place, at 8 o'clock P. M. Dr. C. P. Strong: "The Relief of Salpingitis by Drainage of the Uterus."

Dr. G. Haven: "Three Cases of Craniotomy," done for different reasons, during the month of September, at the Boston Lying-in Hospital. Election of officers.

G. G. SEARS, M.D., Secretary.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT, SECTION IN OBSTETRICS AND GYNECOLOGY.—A regular meeting will be held at 19 Boylston Place, on Wednesday, January 13, 1892, at 8 o'clock P. M.

There will be a discussion on "The Pathology, Diagnosis and Treatment of Pelvic Inflammations," which will be opened by Drs. Fitz, Chadwick, Davenport and Cabot.

N. B.—Members of Suffolk District who wish to receive notifications of the meetings of this Section will kindly inform the Secretary to that effect.

GEORGE HAVEN, M.D., Secretary, 92 A, PINCKNEY ST.

THE SECOND INTERNATIONAL CONGRESS ON DERMATOLOGY will be held in Vienna from September 5th to 10th, 1892. In connection with the Congress there will be an exhibition of all objects connected with the pathology and therapy of diseases of the skin.

PROF. M. KAPOSI, President.

DR. G. RIEHL, General Secretary.

RECENT DEATHS.

HENRY O. MAYO, M.D., Captain and Medical Director, United States Navy, retired, died in New York, January 1st, aged seventy-two. He was appointed assistant surgeon in 1846, surgeon in 1859, medical director in 1872, and placed on the retired list in 1873, since which year he has lived in New York.

JAMES AYER, M.D., M.M.S.S., died in Boston, December 31st, aged seventy-six. Dr. Ayer graduated from Bowdoin College in 1834, and from the Bowdoin Medical School in 1838. He came to Boston in 1846. Among the institutions in which he was specially interested were the Discharged Soldiers' Home and the Lying-in Hospital, of which he was a trustee for many years.

ALFRED RICHET, M.D., of Paris, who has been surgeon in the hospitals of Lourcine, St. Antoine, St. Louis and La Pitié, a member of the Academy of Medicine and of the Legion of Honor, died December 31st, aged seventy-five.

BOOKS AND PAMPHLETS RECEIVED.

The Columbia Daily Calendar for 1892. Pope M'F'g Co.

Eighteenth Annual Report of the Maternity Hospital, Philadelphia, 1891.

The Application of Sacral Resection to Gynecological Work. By E. M. Montgomery, M.D., Philadelphia. Reprint. 1891.

Original Articles.**A BACTERIOLOGICAL EXAMINATION OF THE BOSTON MILK-SUPPLY.**BY W. T. SEDGWICK AND JOHN L. BATCHELDER, JR.,
Massachusetts Institute of Technology, Boston.

It is well known that milk, especially as it is found in large cities, is usually swarming with living bacteria. Most of these are probably harmless vegetables, nevertheless they constitute a host of organisms entirely foreign to the milk itself. The so-called "pure" milk ordinarily obtained in Boston, even when it has not been tampered with, frequently contains in a teaspoonful millions of these microscopic vegetables luxuriantly thriving in a soil most favorable for their development. Moreover, although themselves invisible, they do not fail to produce obvious effects. The souring and chemical decomposition of the milk which soon appear are due exclusively to their vital activity, and the milk which was originally sweet, and which in their absence remains forever sweet, becomes, owing to their activity, sour and chemically decomposed. In this condition it has important uses, but it is no longer "fresh" or "sweet" or "normal" milk. Under the worst conditions milk may actually be delivered to the consumer nearly or quite sour; and we have ascertained that in Boston it is regularly and systematically delivered to the great majority of consumers comparatively well advanced towards this condition.

It is with this aspect of the subject only that we shall deal in the present paper. We shall show, in the first place, that the normal milk of the cow contains no ordinary putrefactive bacteria; we shall next discover the source of the swarms of bacteria which infest ordinary city milk; we shall then briefly consider the bearing of these phenomena upon the public health, and the possibility of remedying the present conditions.

It will be observed that we are not now dealing with the specific germs of disease. It is well known that milk is an excellent food for many kinds of bacteria, and this, added to the fact that it is one of the cheapest and most trusted of food-stuffs, makes milk, when infected with pathogenic organisms, a peculiarly dangerous vehicle for the transmission of infectious diseases. Cow's milk, when once infected with the specific organisms of disease is probably a medium far more dangerous than an equal volume of infected water, since, for many bacteria, it is a much more favorable soil. With this aspect of the subject, however, we shall in this paper have nothing to do. We desire simply to show how far the milk in Boston regularly differs in bacterin from the normal; and to discover the causes of this difference. The methods employed for this more general inquiry have not been adapted, or intended, for the discovery of the exceptional cases of contamination of the milk with the specific germs of such diseases as tuberculosis or typhoid fever.

Chemical examinations, both official and unofficial, of the milk-supply of Boston have been, and continue to be, repeatedly made, but no systematic and extensive bacteriological examination has hitherto been reported. It appeared to us therefore, highly important, at least from the scientific standpoint, to inquire what information might be gained by a series of bacteriological examinations systematically conducted. To

this end, during the past two years, we have made many hundreds of examinations of Boston milk, of which the principal results are here published for the first time.¹

In order to discover the bacteriological changes which milk undergoes in its journey from the cow to the consumer we have made a series of examinations of milk as it flows from the cow; of milk as it is carried from the stable; of milk as it is found upon the tables of well-to-do country families; of milk as it arrives in Boston; of milk as it is sold from wagons, in groceries, etc.; and finally, of milk as it exists upon the tables of well-to-do city families. The main object throughout was to discover the source and significance of the bacterial swarms which infest city milk. To this end our experiments began with the cow.

I. NORMAL (UDDER) MILK.

That milk must be regarded as *normal* which is drawn from the teat of a healthy cow. In such normal, or udder, milk, we have found no trace whatever of bacteria. The same result has been obtained by some previous observers, while others have found it difficult or impossible to obtain milk from the cow free from all germs. All observers, however, agree that very few, if any, organisms are present in normal cow's milk, and that the germs sometimes observed have probably been due to defective manipulation. Without special precautions, we, also, have found it extremely difficult to draw milk from the cow's udder *entirely* germ-free, and at first we failed to get it absolutely sterile. By a special method, however, we have succeeded in drawing, with ease, from the cow's udder, absolutely sterile milk. From this fact and the similar observations of others, there need be no question that the normal milk of the cow is free from bacteria. A consideration of the mechanism and physiology of secretion will show that this, for the healthy cow, is entirely reasonable. Normal cows secrete milk; they do not secrete bacteria.

A method by which this fact can be easily established deserves description. If one seeks to draw normal milk, germ-free, by hand, and milks in the ordinary way, into a sterilized bottle, he will usually fail to obtain sterile milk. The reason appears to be that the act of milking shakes the udder and throws down from the skin of the animal a shower of dust and germs which pass into the bottle with the milk. By the use of the silver catheter or so-called "milking-tube" of veterinarians, however, this disturbance is completely avoided. The milk flows, without action of any kind on the part of the observer, in a strong and steady stream, of which a portion may be easily caught by a merely instantaneous exposure to the air.

The precise method of procedure is as follows: A clean cow is selected and the operation should be attempted only in a clean stable. Care being taken to avoid disturbance of the bedding (if any) the skin of the hind quarter and of the udder are washed. The teats are then wiped dry and milking in the ordinary fashion is begun, in order to start the secretion. A pause is then made and while the dust of the stable settles, the milk accumulates in the udder. The catheter, previously sterilized by heat, is drawn from a plugged test tube and cautiously passed through one of the teats into the udder. The milk instantly flows away from the

¹ An abstract of this paper was read by J. L. Batchelder, Jr., before the Boston Society of Medical Sciences, March 31, 1891.

resting udder, through the catheter, in a strong and continuous stream, from which a series of samples can readily be taken. Many of these, in our experiments, proved, if planted at once, perfectly sterile. Others showed a very few colonies which were plainly due to aerial contamination.

We have not sought to determine the presence or absence of tubercle bacilli in normal milk, as this was foreign to our investigation. At the same time it is clear that this method might well be applied in such an investigation. The detection of tubercle bacilli in milk has hitherto depended, not on cultures, but upon the differential staining of cover-glass preparations, and upon the infection of guinea pigs with cow's milk. These experiments have sufficed to show the presence of such bacilli in the milk, but they do not tell us whether the bacilli have come from the udder or not. The mere detection of the germs of tuberculosis in cow's milk does not prove that these have proceeded from the cow's udder. They may have come from the dried saliva or excrement of the cow, and have fallen in during the act of milking. By the method just described, however, it might perhaps be found possible to obtain more valuable results, and even to make test cultures of diseased milk.

II. PURE COUNTRY MILK.

In the previous section we have shown that healthy cows give milk which, examined by the usual methods, is absolutely free from germs. It appears, therefore, that the normal milk of the cow is milk not only undecomposed, but free from the germs of decomposition. "Pure" milk may possibly be defined as milk which has not been watered. It is sometimes so defined. But normal milk cannot be defined in this way, and in the considerations which will follow the high standard of normal milk must be kept in view. Clearly, also, the cow is not the source of the hosts of bacteria regularly observed in Boston milk. We therefore turned to the examination of milk as it is found upon the tables of well-to-do country families; that is, to the study of unquestionably "pure," country milk. Such milk is generally comparatively fresh, and is often served only a few hours after the milking. Nevertheless our results show that such milk is generally rich in bacteria, though the numbers are much smaller than in ordinary city milk. We then made the following experiment: milk was drawn from a clean and well-kept Holstein cow in an unusually decent stable. The normal milk of this cow had already been repeatedly proved to be sterile. Milk drawn by hand from this cow with great care into sterilized bottles, and planted quickly, yielded, as an average of several trials, 530 bacteria per cubic centimetre. When, however, the milkman used the ordinary milk-pail of flaring form, seated himself with more or less disturbance of the bedding, and vigorously shook the udder over the pail during the usual process of milking, we found that the numbers were very much higher, namely, an average of 30,500 per cubic centimetre, at the end of the milking. When such milk is found upon the tables of country families a few hours later, it usually shows still more bacteria, doubtless because those with which it was seeded have had time to multiply. The average of fifteen such samples from the tables of families in Jamaica Plain, Cambridge and Auburndale was 69,143 per cubic centimetre. In these cases, moreover, the conditions of

the cows and of the stables were exceptionally good, while the milkmen were much more than ordinarily clean and careful.

It follows from these results that there are two principal sources of the bacteria in milk; namely, contamination during the act of milking, and the natural multiplication of the bacteria thus introduced during the interval between milking and the consumption of the milk. The result of these investigations was to show that even under the most favorable conditions cow's milk as ordinarily drawn becomes, almost necessarily, infested with hosts of bacteria at the very outset. Under worse conditions, with unclean stables and dirty milkmen, to say nothing of half-cleaned pails and cans, it is easy to understand why milk swarms with bacteria: and, if we allow time also, the wonder is, not that it contains so many germs, but rather that it is still potable at all.

When we reflect upon the indescribably filthy condition of many cow stables; upon the fact that the cow's udders and flanks are not infrequently covered with flaking excrement; upon the quality of the men employed to do the milking, etc., etc., it becomes a simple matter to understand how this rich, animal fluid — sterile at the start, but drawn by unclean hands into half-cleaned pails, and meantime sprinkled from above by the dust of the stable, by hairs, dandruff, dirt and particles of excrement from the skin and udder of the cow vigorously shaken by the milker or brushed by his hat — becomes infested with organisms. That these multiply swiftly and enormously in the warm and rich fluid, well aerated by the act of milking, is also a natural consequence of favorable conditions.

III. BOSTON MILK.

If, now, we turn to the condition of city milk as exemplified by that delivered in Boston (and we have no reason to suppose that Boston is worse in this respect than many large cities) we find, as might be anticipated, a marked increase in the numbers of bacteria over those found in country milk. The average number of bacteria found in fifty-seven samples of Boston milk in the spring of 1890 was 2,355,500 per cubic centimetre (roughly equal to a cubic one-third inch or to one small thimbleful). These samples came from different parts of the city. Thus:

Charlestown,	8 samples averaged . . .	4,222,500 per c. e.
Jamaica Plain,	10 "	3,259,600 "
Roxbury,	17 "	1,874,200 "
South Boston,	9 "	2,778,000 "
North End,	6 "	708,100 "
Back Bay,	7 "	1,189,800 "

These samples were obtained directly from the milk wagons and planted at once. We are indebted to Dr. Charles Harrington, Milk Inspector of Boston, for much courteous assistance in procuring these wagon samples.

From groceries we obtained sixteen more samples, in which the average number of bacteria was 4,577,000 per cubic centimetre. The groceries usually have older milk than that found in the wagons, which readily accounts for the higher numbers of bacteria.

Ten samples collected from well-to-do families upon the Back Bay showed an average of 1,438,000 per cubic centimetre. The lowest number found in Boston milk supplied in the ordinary way was 30,600 per cubic centimetre. With special care, however, milk can be, and is now in a few cases, regularly delivered

in Boston with much greater freshness and purity than these figures indicate.

It will be seen at a glance that the milk-supply of Boston is very rich in bacteria. Much of the milk arrives from distant point by rail, and is therefore necessarily more or less stale. Forty-four samples of this so-called "railroad" milk from one dealer showed that the milk, even upon its arrival, contains on the average more than 500,000 bacteria per cubic centimetre. The extremes in this case were 5,664,000 and 2,200. In another set of ten samples the milk on its arrival in Boston averaged 371,000 per cubic centimetre.

Our experiments have been repeated in 1891, and the results prove that the figures for 1890 are not exceptional. There are some indications that, as might perhaps be expected, watered milk contains fewer bacteria than unadulterated milk. "Skim" milk, on the other hand, probably on account of its staleness, is sometimes very rich in organisms, though this is not always the case.

IV. INTERPRETATION OF THE RESULTS.

We have now shown that the normal milk of the cow is free from bacteria. We have also found that the milk-supply of Boston is exceedingly rich in bacteria. We have further discovered that these bacteria are principally introduced during the operation of milking in unclean stables, and that they afterwards multiply enormously in the milk, in which they effect important changes of decomposition. Two principal conditions thus co-operate to cause the extraordinary abundance of bacteria in Boston milk; namely, uncleanness and staleness. The former condition furnishes the seeds of decomposition; the latter the time for their development. Their co-operation produces a fluid widely different from normal cow's milk.

It remains to inquire what is the probable effect of this condition of the milk-supply upon the health of the community. Here we are almost completely in the dark. There can be no question that much of the milk is consumed when cooked, and even when raw without the least apparent injury and with great apparent benefit. But it is probably also true that the use of stale and partially decomposed milk charged with living bacteria, has its effects upon invalids and children, and particularly upon infants, and that these effects are not always beneficial. It is possible that one explanation of the high mortality of children under five years of age, and especially of bottle-fed children, is to be sought for in this direction.

It will not do to argue, because healthy adults drink polluted milk without obvious injury and with evident benefit, that invalids and infants may safely do the same. In order to learn the consequences of a battle, the investigator must examine not merely the survivors; he must consider also the fallen. If it be admitted that infants, children and invalids require normal cow's milk it cannot be denied that they are now rarely, if ever, fortunate enough to get it. Many parents who are fastidious to the last degree concerning their own wine or table-linen, provide for their children, cow's milk which is both stale and filthy. It is safe to say that if our soups or drinking-water were drawn from cows, in remote and obscure stables, by ordinary milkmen, and shipped, adulterated and delivered as our milk is, we should appreciate and resent the pollution. At present, however, so far as mere pollution is concerned,

it is probably true that milk is actually improved by the addition of pure water. The public inspection of milk in America is usually directed mainly to the prevention of fraud; rarely, if ever, to the question of pollution, or except in a very general way, to the protection of the public health.

"One point deserves in the future much greater attention. This is the *pollution* of milk. No food material can be so much polluted as milk. If any one will compute how much cow's excrement an infant swallows, and how much excrement an adult consumes in drinking the sewage-polluted water of the Isar, he will find that the latter is by far the better off."

Dr. Sohlet, the author of the foregoing paragraph, has lately urged that milk be examined not only in respect to its solids and fats, but also as to its contents in filth, after a method employed by Professor Renk, of Halle. The latter found that the public milk-supply of Halle was polluted by very considerable amounts of filth which settled to the bottom of the vessel containing the milk, and by microscopical examination proved to be largely cow's excrement. The average of thirty tests showed fifteen milligrams per litre, or fifteen parts per million, of such filth deposited by the milk of Halle. In Leipzig milk, Renk obtained 3.8; in Berlin, 10.3; in Munich, 9.0 milligrams of similar filth deposited per litre. He found the bacteria in the Halle milk-supply to vary from 6,000,000 to 30,000,000 per cubic centimetre, a result agreeing well with its unclean condition. It may be remarked in passing that the sewage of American cities seldom averages more than 1,000,000 bacteria per cubic centimetre.

V. REMEDIAL MEASURES.

It is clear that the improvement of the conditions indicated above must consist in greater cleanliness in milk production and less delay in its delivery. So far as pollution is concerned it is possible to make great improvements by requiring cleaner stables; those which exist at present being often (from the standpoint of mere decency) simply abominable. The cows might also be kept much cleaner and, if necessary, washed above and upon the udder with warm water before milking, or at least cleaned and groomed as horses have long been. The milkers might be compelled to have clean hands, and taught to avoid pollution of the milk. That the milk-pail might be improved, and even kept partly covered, has been demonstrated by at least one invention now actually in use.

If the milk could thus be kept decently clean and nearly free from bacteria—the seeds of decomposition—and then quickly cooled to a low temperature its decay would be very slow, and its "keeping qualities" would be greatly increased. It could afterwards be transported over even long distances without damage, provided only that a very low temperature were constantly maintained. Under existing methods, however, quick delivery is essential, since the milk is richly seeded with filth at the very outset, and only imperfectly chilled during its journey to the consumer. To permit of all these improvements it is possible that a higher price might have to be paid for clean and fresh milk as is now done for fresh-laid eggs.

Finally, it does not seem unreasonable to urge that the whole matter of the public milk-supply deserves at least as careful attention from the public sanitary authorities as does, for example, the public water-sup-

ply. If questions of uncleanness and staleness do not seem to justify this conclusion, it is only necessary to add, inasmuch as milk is now believed to be one of the important vehicles for the distribution of tuberculosis, scarlet fever, typhoid fever and other infectious diseases, that the question of its possible infection is always of the highest importance. The time must soon come when our present neglect of the milk-supply problem shall cease, and when we shall no longer be satisfied with chiefly preventing the cheating connected with its dilution by water.

SOME USES OF THE STOMACH-TUBE.¹

BY E. M. BUCKINGHAM, M.D.

DURING the past few years it has happened to be my fortune to use the stomach-tube a limited number of times in cases of various kinds; and while the number of cases has been small, much smaller probably than has come to some other members of the Society, yet it has given me some positive ideas on the subject. If, as I believe, the use of the tube is not very common in this neighborhood, possibly a report of the cases may not be without interest.

One of the first things that struck me in the matter was the ease, to the physician at least if not to the patient, with which it is introduced, provided always the tube is held in one vertical plane and in the median line as it passes behind the tongue. I mean that the only curve should be from above downward, and that there should be none from side to side, in which latter case the tube is very apt to catch. I think, too, that milk, while sometimes used as a lubricant, is not so good as something more tenacious, oil for instance. The operation is somewhat facilitated by the patient's swallowing, but the operator can gain time, and save discomfort to the patient, by pushing gently at the same time.

A second point is that it is extremely disagreeable to the patient. One hears of patients who become accustomed to it or who even at first make little objection. I have not seen such, the only exception to this statement being the case of one hysterical woman. On the contrary, the disagreeable nature of the treatment is sufficient in my opinion to cause it to be avoided except where its use is imperative; and this rule will, I think, exclude it in some cases where recovery might be hastened by its use, but where other methods, although slower, promise to be effectual.

A third point is, that, while the tube is commonly introduced with the patient sitting, and the head thrown back in order to straighten the passage from mouth to stomach, yet it is sometimes, at any rate, equally easy to use it with the patient flat on the back and that the patient must be deeply narcotized indeed, for this position to create danger from water flowing toward the mouth in quantity to do harm by entering the glottis.

A few cases of nervous dyspepsia in my care have been helped, as perhaps they might have been equally by electricity or any other course which appealed strongly to the imagination.

Lastly, as has been much more abundantly proved by others, cases of catarrh of the stomach, with or without constriction of the pylorus, are capable of much benefit from systematic washing out.

The following cases all occurred at the City Hospital, and would not be reported as yet, but for the slowness with which I have been able to collect them. During a recent continuous service of about seven and a half months divided between out-patient room and wards, although on the alert for opportunities, I have met but two cases in which the advantages of this treatment seemed to me to overbalance its annoyances. The cases are arranged for convenience and not chronologically.

CASE I. A man was brought into the hospital by the police, completely unconscious; pupils equal, and with slow reaction to light; face flushed; no rigidity. The breath had a peculiar odor which no one present was willing to say was alcoholic. Urine obtained by catheter was not albuminous. There was no history, the man being brought in as the police found him in the street. The tube was passed with no difficulty the patient being flat on the back; and the stomach was washed repeatedly with a quart of water at a time. There was no overflow of water. This patient proved to have been drinking enormously, and was discharged the next day. The only point of interest about it was the ease with which it was done.

CASE II. A woman, picked up by the police in Franklin Park totally unconscious, with an empty landau bottle by her. Symptoms of extreme opium-poisoning on entrance to hospital. Urine obtained by catheter contained albumen. She was immediately placed by the house-officer on her back with the feet elevated, on account of heart weakness. Artificial respiration and faradism were applied. Coming into the hospital immediately after, I attempted to wash out the stomach in this position, if possible, and found it difficult to get the tube into the stomach, on account probably of the resistance of gravitation to the flexible tube. After it was inserted water introduced slowly began to run out by the mouth, and the attempt was abandoned until the patient had been placed horizontally, after which the stomach was washed with no more trouble. The woman died some two hours later. In this case the whole interest lies in the difficulties made by the position of the patient.

CASE III. This is somewhat unusual. A man of forty-five was admitted to the hospital on the eighth or ninth day of typhoid. He had a temperature of 104°, which was not much affected by cold sponging, and he was rather weak. He was given an ounce of rum every eight hours. On the second day after admission the temperature rose to 105°, and fell suddenly during the night. At my next morning visit the nurse had just reported that he had ceased to answer questions and could not swallow. This was a sudden collapse in a man who had not been much stimulated. There was little hope of treatment by the rectum, and I introduced a tube into the stomach and poured in about a tumblerful of rum and carbonated water in equal parts. In the course of fifteen minutes he had revived and was able to swallow; most of this mixture was retained, although a little was vomited. He was stimulated heavily for a few days, and finally recovered. I am by no means sure that the result was better than would have followed subcutaneous stimulation.

CASE IV. This case, and perhaps the next one, belong to a different class. A woman was discharged from the hospital partly relieved from an attack of great debility and hysteria brought on by overwork and sorrow. A week later she returned, salivated by

¹ Read before the Suffolk District Medical Society, October 31, 1891.

persistent use of calomel as a cathartic. Her appetite had been ravenous, but now, because of her sore mouth, she was unable to eat, although hungry. After recovery from mercurial stomatitis, she continued unable to eat because of pain in the epigastrium; which pain I believed to be hysterical, but she believed it to be due to extension downward of inflammation from the mouth. Her stomach was washed out once at the suggestion of the house physician Dr. Robinson, and the good effect was immediate. He tells me that she wanted it done, and that it did not appear to be disagreeable. I was not a personal witness, but can readily believe that he was right. This is the only case of the series, however, in which patients have not made more or less objection.

CASE V. American woman of forty. Two hours after eating, gnawing pain in stomach and occasional nausea, which had continued for four years; during which time she had menstruated too freely and too often; she having a uterine tumor which was believed to be fibroid. She had had a similar gastric trouble thirteen years before. There was a strong family history of cancer, and she was anxious about herself. She had entered the out-patient room during the service of my colleague Dr. Withington, and after other treatment he had washed out the stomach, for the sake of the local stimulating effect. The effect had been good, and I continued it at intervals of a week for about four months. She disliked it, but showed courage in persevering, and reported herself as continually getting better. A part of her strength being lost with each menstruation, she was twice sent into the hospital at such times for observation. Dr. Mason, in whose service she first entered, caused the stomach to be washed every day for a week, and afterward less often. She remained in his service for about a month, remaining in bed during menstruation, without serious flowing, and gained in every way, although the stomach continued to have bad days. The following month she again entered the hospital. A little later she became discouraged, pain returned, and she passed out of sight. After an interval of a year and a half I learned that she had been very sick since leaving the hospital, was said to have got entirely well in less than a year, and had moved, no one knew where. The benefit of washing in this case seems to me to have been entirely in its effect on the imagination.

The remaining cases are of organic disease of the stomach.

CASE VI. Man of thirty-six. Had been a drinker. For six months had complained of his stomach — eructation, vomiting and tenderness. Had got relief from beer and from charcoal. Percussion showed a large area of stomach resonance. The stomach was washed out twice, each time with marked relief to symptoms. There was no undigested food and little mucus in the effluent. My term of service ending, he passed from my observation; but I know that he died within a few months, of cancer of the stomach, which diagnosis was verified by autopsy.

CASE VII. Probably cancer of pylorus, but no autopsy. Vomited after meals for a year, dejection every two or three weeks before entering hospital. Mass in region of pylorus about four inches in diameter. Soon after entering, had vomited about two quarts of light-brown fluid containing undigested food. Being fed entirely by rectal enemata and still suffering from intense nausea, I washed out the stomach, to his great

relief, removing from one to two quarts containing much undigested food that must have been taken at least three days before. On the following day the stomach was again washed, getting away more undigested food with a dark sediment, and he became very comfortable. From this time to his death, in about two weeks, there was no complaint except of weakness. He became unwilling, however, to take any food by the mouth lest it should again necessitate the use of the stomach-tube, the advantage of which he appreciated, but to which he had a great repugnance notwithstanding.

CASE VIII. A heavy drinker, with frequent vomiting, the ejected matter consisting largely of mucus. This patient vomited out the tube before it was quite inserted, and again while water was running through it. It was introduced a third time and the stomach thoroughly washed, the patient frequently retching during the process. He never presented himself for a second treatment.

CASE IX. Frequent vomiting of much mucus apparently dependent on improper food. Washed; getting rid of much mucus. No second visit.

CASE X. Man of twenty-eight. Emaciated, debilitated, vomiting mucus for six weeks. Owing to his occupation he could not attend to himself regularly, nor could he enter the wards. In addition to other treatment he was washed three times in twenty days, but he got no better, and ceased to attend. Probably this case is of no value, owing to irregularity of treatment.

CASE XI. Is the last and most satisfactory of the series, — a man of thirty-nine, of good habits, a tailor, whose sickness began with severe diarrhoea and gastric disturbance. These were not treated, he remaining at what he called unusually hard work. He recovered from diarrhoea, became somewhat constipated, and suffered from pain after eating, anorexia and nausea. After a while he gave up work, and for fifteen months spent most of the day on the bed because of weakness. He had had many physicians, the last of whom, a perfectly competent man, had treated him for some months without benefit. His present condition was much emaciated, flatulent, and with stomach resonance extending nearly or quite to the umbilicus. For two months the stomach was washed with a weak, hot solution of sodium bicarbonate in water as late after breakfast as possible, and at first three times a week. The first few washes brought away undigested food and much mucus, nearly clogging the tube. These diminished with every washing, undigested food disappearing first. The diet was attended to, as it had been before. During the first week, aromatic sulphuric acid was given after dinner. In the second week this was changed to sodium bicarbonate thirty grains in hot water on rising, a means of getting rid of an over-supply of mucus which is sometimes efficient by itself. In the third week, the stomach being now cleaner, this was changed to tincture of nux vomica after meals. At the beginning of the fourth week the effluent water was nearly clear, and after this, washing was done less frequently. Appetite improved; and in the second month he began rowing for exercise; soon worked half-time at his trade; and in two months was discharged well.

Three years later he told me that he had been well ever since. Here was a sequence of fifteen months' sickness, two months' treatment with steady gain that

did not begin before treatment, and three years of health. Recovery was due to washing, not to collateral treatment, for he had been through much of that before.

Clinical Department.

TUBAL PREGNANCY: A CASE.¹

BY G. H. WASHBURN, M.D.

Mrs. G. is a pale, slender, rather delicate woman of thirty-five years. She has been married seventeen years, and has never been strong since the birth of her first child. For the past nine years she has been afflicted with chronic bronchitis, lasting the whole winter, anyway, and sometimes longer.

She has had four children, sixteen, fourteen, twelve and nine years ago respectively. She describes the labors as all quite easy. She was attended in every case by a midwife. All her children were thin, and their heads not specially large.

Her first labor lasted about three hours — from the commencement of the pains to the birth of the child.

Her second pregnancy was characterized by considerable pain and vomiting, etc., and at about the fourth month she had to go to bed. It was four or five weeks before she was able to get up again. The labor lasted only about two hours.

The third pregnancy was not so uncomfortable as the second. The labor lasted scarcely two hours, and the child was born before the midwife could get there.

Her fourth labor was the hardest, lasting about six or seven hours.

She has had one abortion, occurring five years ago. This was somewhat peculiar. She went along for about six weeks with all her usual feelings and discomforts accompanying pregnancy. Then, very curiously, these ceased, but there was no return of the catamenial flow. There were, however, little driplets of flow off and on at irregular intervals, and considerable leucorrhœa. After six months of this she went to a physician who "scraped the womb," and got out considerable bad smelling débris. After that her menstruation returned and was regular until the present pregnancy.

Menstruation commenced when she was thirteen or fourteen years old; it has appeared regularly every twenty-eight days until the past year, when it has been every twenty-six days. The flow lasts six or seven days, during the first three of which she uses about three napkins daily, the rest of the time one or two a day. There is some pain for two days before, and for the first two days of the flow.

There is some *leucorrhœa*, thick, viscid and yellowish, non-irritating. This would be discharged in gushes, but the amount was small — only about a couple of drachms — and there was no pain immediately preceding the discharge.

The patient has never felt well since the birth of her first child. There has been pain in the lower part of the back, bearing-down pains and other discomforts. The bearing-down pains were only occasional at first, coming perhaps after some over-exertion or long walk. They have been increasing, however, and lately have been worse and more persistent.

Two years ago, without any cause that she can recall, she began to have a pain in the right groin; for the past year this has been constant, and occasionally it has extended across to the other side. Her pain and discomfort is worst when she is on her feet.

There has also been a spot in the right inguinal region which, for the past two years has been very tender on pressure. It has felt specially sore and sensitive after going to bed, so that even the pressure of the bed clothing upon it has been painful. This small sensitive area has been much more comfortable during the catamenial flow.

Bowels have been quite regular.

Micturition about normal.

Urine normal.

Sleep has often been disturbed by pain. She has generally wakened in the morning feeling tired instead of refreshed.

Appetite and digestion have been good.

With the exception of some frontal headache her general health has been quite good the past summer.

I saw the patient the last of September, having been called in consultation by Dr. Gillespie. Her last menstruation had ended seven weeks previously. Twice since that, however, she had a little show of blood, the last time being about September 1st. The middle of August she had begun to have nausea and vomiting. This soon became almost constant. She could retain nothing on her stomach except some broth, and at times that would come up too. When she took nothing a clear, frothy, acrid fluid would come up by mouthfuls. Her sleep was disturbed by this continual regurgitation. Her strength, color and flesh were rapidly wasting, and she was unable to leave her bed. Dr. Gillespie had tried all the usual and unusual remedies in a vain effort to relieve the vomiting.

Examination showed a uterus considerably enlarged, especially in its length, and seemingly farther advanced in pregnancy than the date of the last menstruation would warrant one in believing. The uterus was retroverted (about the second degree) and apparently tipped to the right also. There was a large tear of the cervix and perineum. The lips of the cervix were everted and much eroded. Pressure in the right inguinal region gave some pain. The supposition was that the malposition was the cause of the vomiting. The uterus was replaced, in the knee-chest position, and held up by a packing. Scarcely two days later, there was not a particle of relief to the vomiting. However, owing to the extensive tear of the perineum the packing had slipped somewhat, allowing some descent of the uterus. Then a pessary was adjusted which held the uterus up in very good place. Still there was not the slightest letting up of the vomiting, and the steady failure of strength continued.

The cervix was now painted with Churchill's tincture of iodine. The effect was to cause marked improvement in the local condition, but none whatever in the vomiting.

As all these expedients, medicinal and mechanical, had failed utterly to produce the slightest amelioration in the patient's condition, as she was very weak and rapidly failing, and as, moreover, the damp weather was impending, when she might look for the advent of her annual bronchitis, it was deemed best to induce an abortion. For this purpose a large bougie was introduced four inches into the uterus and fastened there, due antiseptic precautions having been taken. For a

¹ Read, by invitation, before the Obstetrical Society of Boston, November 14, 1891.

few hours after its introduction it caused some pain or pains in the right side and some discomfort in the back. For the remainder of forty-eight hours it did not seem to have any effect, locally or on the vomiting.

It was now determined to curette the uterus. The patient did not wish to take ether — she was a plucky woman — and as the uterus did not seem very sensitive, we went ahead without it. The os dilated readily with a Goodell-Ellinger dilator. A broad, dull curette was used. The uterus was found about four inches and a half deep, but at first appearance there was nothing in it; soon, however, a resistant mass was felt up in the right corner; scraping brought away only a few bits of tissue. An effort was now made to bring down something with the placenta forceps. Presently something was grasped by the forceps. Steady but gentle traction was followed by a sudden gush of several ounces of clear fluid, but no tissue was brought down. There was not much bleeding.

It was now deemed best to discontinue any further manipulation. A strip of iodoform gauze was introduced into the uterus and packed lightly into the vagina. Instructions were given to remove this the next day.

The night following the removal of the gauze severe, cramp-like pains came on, increasing in intensity. These lasted for about five hours, then ceased quite suddenly. They did not call any one till morning when Dr. Gillespie was summoned. He found the legs of a small fetus protruding from the os uteri. Passing his finger into the uterus as far as possible he found a long mass extending up into the right cornu. Grasping the fetus and its envelope he drew down a cigar-shaped mass about four inches long, and about two inches thick in its largest diameter, the surface a little convoluted, the fetal sac hanging from the larger end.

Placenta as seen from behind, as it came from the right tube. Specimen is a little shrivelled by being in alcohol. A shows the cavity of the sac, held open by two small splinters. The whole placenta was in the tube, and the sac protruded somewhat into the cavity of the uterus.

I did not see the patient till that afternoon. Vomiting and even nausea had entirely ceased and have not returned since.

Convalescence has progressed satisfactorily without rise of temperature or other untoward symptom.

Menstruation appeared on the 5th of November lasting until the 11th. There have been two gushes of blood, but the flow altogether has amounted to only twelve napkins.

Examination on November 13th, just four weeks from date of expulsion of fetus and membranes, shows the following condition: Uterus retroverted, second degree or a little more, cavity not measured, but bimanually shows that involution has been progressing satisfactorily. The left tube and ovary feel normal. The right ovary not felt, but the tube seems about the size of the little finger and twisted like a knuckle of intestine, somewhat tender on pressure. She has been gaining in strength, and is now about her household duties.

To review the case briefly:

There were no attacks of severe pain, in fact there was no more pain experienced than had been present for the past two years. There were no attacks of bleeding, unless you would call such the two times when there was a slight show of blood.

The important fact which was noted in the first examination was not given sufficient weight as showing a tubal pregnancy. I refer to the apparently lengthened-out shape of the uterus, out of proportion to its diameter at that stage of pregnancy, the enlargement, moreover, extending to the right.

There was present persistent vomiting, unrelieved by medicinal or mechanical means, reducing the strength of the patient so as to demand operative interference.

The introduction of the bougie was unattended by results.

Not only did the curette fail to bring away much of any tissue, but the placenta forceps did not grasp anything until they were passed well up into the right cornu of the uterus.

Evidently the whole placenta was in the tube, but a part of the sac protruded into the uterine cavity. The specimen proves the correctness of this supposition.

The traction and opening of the sac, and the stimulating of contractions by the introduction of the iodoform gauze into the uterus, loosened the placenta and allowed the uterine contractions to force it down.

Finally, a large tube, the enlargement most apparent at the uterine attachment, remains to show the site of the placenta.

It is interesting to note the immediate cessation of the vomiting as soon as the uterus was emptied.

A CASE OF PROBABLE TUBAL PREGNANCY.¹

BY EDWARD REYNOLDS, M.D.

On the 6th of last August, I was called to the country to take charge of the case of Mrs. X., secundipara, with the following previous history.

In her first pregnancy, she was afflicted with extremely severe vomiting. Becoming a patient of Drs. W. H. Baker and F. H. Davenport, she was discovered to have a retroversion of the uterus, which was relieved with much difficulty by prolonged packing of the vagina. After the relief of the displacement, the vomiting gradually subsided, and she went to term without further accidents, and was safely delivered after an easy labor.

During the first weeks of her second pregnancy, her social duties subjected her to considerable fatigue: and when a little less than two months advanced, she was

¹ Read before the Osteatrical Society of Boston, November 14, 1891.

again troubled by quite severe nausea and vomiting, which became steadily worse until I saw her, at which time she was a little more than three months advanced. She had then been confined to her bed for nearly a fortnight, had failed to retain any considerable amount of food for more than ten days, and had been vomiting excessively for five or six days, during which time she had retained upon her stomach no food whatsoever, and had been nourished solely by enemata. The rectum was becoming intolerant. She was already very weak; the pulse was about 110 or 112. Any attempt to move in bed, any noise or jar in the room, in fact, any external stimulus, caused attacks of vomiting, which were seldom fifteen minutes apart. No local examination had been made. I found the uterus retroflexed and retroverted, the fundus upon a level with the cervix, and not readily to be raised. Under ether, it proved to be impacted between the utro-sacral ligaments, but it was not adherent and was readily raised into position by taxis.

The uterus seemed to me to be slightly irregular in shape, the right side being much more prominent than the left, and the right cornu seeming to extend into the broad ligament, in a way which at once suggested the possibility of an interstitial pregnancy, or of pregnancy in one horn of an asymmetrically developed uterus. I am bound to say, however, that although this possibility was suggested to me at the time, I felt that the results of examination were not sufficient for the formation of the diagnosis.

The uterus was easily retained in position by the insertion of a pessary, and after the recovery from ether there was no vomiting for several hours. It then recurred, though in a somewhat less severe form than before. I could detect no erosions upon the cervix uteri.

The patient was removed from an extremely noisy room in the hotel to one in which comparative quiet could be obtained, and the next day was spent in the administration of enemata. The vomiting was still distressing, though decidedly less than when I first saw her.

During the next night, she was attacked by sharp, colicky pains in the right iliac and inguinal regions, of a character which she described as closely similar to labor. The attack subsided spontaneously after a few hours, and was not followed by any relief of the nausea. On the following morning, her pulse ranged from 120 to 130 beats per minute, and her exhaustion was extreme.

In the belief that any further attempt to preserve the existence of the fetus would almost certainly result in the loss of both patients, I decided upon the immediate induction of an abortion. The os was found, as upon the preceding day, soft and slightly patulous, and was easily dilated with branching steel dilators to a size which admitted the index finger. The intact membranes presented at a level slightly above that of the internal os, with which they were not in contact; and behind them could be felt the head of the fetus.

Feeling anxious, on account of the uncertain condi-

tion of the right broad ligament, to avoid all unnecessary manipulations, I passed into the uterus the blades of a pair of ovum forceps, and was fortunate enough to succeed in extracting by their use a complete, though badly lacerated ovum. The placenta was fully formed, the size and appearance of the fetus corresponded to a pregnancy of a little more than three months. On again passing the finger into the uterus, I found a condition which I have endeavored to represent in the diagram which I pass around. The evacuation of the uterus was followed by immediate relief of vomiting; the recovery was prompt and uneventful.

The history and results of the intra-uterine examination seemed to me to render it probable that the case was originally one of interstitial pregnancy, which was converted into an approximately normal form by the efforts of nature, during the night which preceded the delivery; and, although I do not consider the diagnosis as by any means established, I think that the rarity of such a condition renders the case worth reporting, and especially in connection with the very interesting and well established instance which Dr. Washburn has detailed to us.

A CASE OF TUBAL PREGNANCY.¹

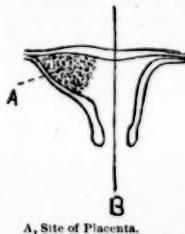

BY F. B. HARRINGTON, M.D.

Mrs. M. J., thirty-three years old, widow, never before pregnant, passed the time of her period by two weeks, when flowing came on with considerable pelvic pain unlike any previous menstrual distress. The discharge was slight but continuous. The pain was at the right side of the pelvis. The flow continued with increasing pain for three weeks when I first saw her. The abdomen was tender and slightly distended. Vaginal examination showed a mass on the right side of the pelvis resembling a dilated tube. There was tenderness and thickening about the mass. The patient was put to bed, and was given opiates and douches. The bloody discharge ceased in about a week, but soon returned again in slight amount. The pain gradually diminished. The bloody discharge ceased entirely in about six weeks from its first appearance. The tumor at the right side of the uterus had increased in size until it was nearly as large as a large lemon. It was still tender to the touch and gave the patient a feeling of discomfort. After a two months rest the patient was much improved in general health, but the tumor remained a source of great discomfort to her.

Removal was advised. The mass was found to be the dilated right Fallopian tube which appeared to contain fetal remains with a considerable amount of bloody fluid. The fetus had probably died at from five to six weeks.

The following is Dr. Whitney's report of the specimen:

"Tube and Ovary." — The portion of tube measured about twelve centimetres, and walls were thickened. About eight centimetres from fimbriated end was a nodular enlargement chiefly opposite the side of the ligament. This measured about nine centimetres in circumference. The surface of the tube was covered with rough fibrous adhesions. The cavity was dilated and shaggy, and the enlargement filled with a villous-looking mass, and from this a thin membranous sac was continued to the fimbriated end, and projected

A, Site of Placenta.
B, Median Line of Uterus.

¹ Read before the Obstetrical Society of Boston, November 14, 1891.

slightly beyond. In this part was a hard reddish nodule the size of a pea which on section showed a small differentiated mass recalling the outline of a very young embryo. Microscopic examination showed round cells with an embryonic arrangement, and at one end was an accumulation of pigment. Microscopic examination of the villous mass showed small finger-like projections similar to those of the chorion.

"The Ovary was small and contained a few retention cysts, but no corpus luteum. It was situated opposite the tube about eight centimetres from the fimbriated end."

The patient made a good recovery.

Medical Progress.

RECENT PROGRESS IN DISEASES OF CHILDREN.

BY T. M. ROTCH, M.D.

GASTRIC DIGESTION IN SMALL CHILDREN, AND IRRIGATION OF THE STOMACH.¹

THE following propositions include the substance of the author's paper:

(1) The presence of completely coagulated casein in the stomach does not warrant one in speaking of the excessively acid contents of the stomach, for a precipitation of the casein from the solution can only happen in consequence of the influence of fermentation and this acts in the presence of an alkaline reaction.

(2) The change of the casein, which has begun to coagulate, to the state of solution with subsequent peptonization is due to the simultaneous action of acid and pepsin, and the stomach takes up the albumen the more successfully and completely the more the quantity and composition of the digestive secretions approach the normal.

(3) Lactic acid must be regarded as a normal constituent of the gastric juice, at least in very young children and in those with whom the diet is exclusively one of milk, and its formation is encouraged by the milk-sugar which is abundant in the milk. This constant presence of lactic acid has its effect alike upon the digestive process and upon the action of microbes.

(4) Hydrochloric acid plays the principal part in digestion, but its determination is not always easy, because the casein of the milk has the property of holding it until digestion begins. Hydrochloric acid may usually be found in small quantities in the stomachs of very small children. As digestion increases in activity, the quantity of hydrochloric acid also increases.

(5) The quantity of acid in the gastric juices of children is relatively very much smaller than in adults, and is conversely as to the quantity of food taken into the stomach.

(6) The average time during which food stays in the stomach of small children is two hours.

(7) Slight mechanical, thermic or chemical irritation of the gastric mucous membrane will increase the acidity of the secreted juice and favor a rapid emptying of the stomach. Alcohol stays digestion, but counteracts fermentation.

(8) The part in digestion which is played by the stomach of the child is an important one, even though

¹ Trotzky: *Jahrb. f. Kinderh.*, xxxii, 4, *Archiv. Pediat.*, vol. viii, November, 1891.

it does not appropriate all the albumen which comes into it.

(9) The anti-microbial properties of the gastric juice are undoubtedly, and due to the presence of free acid, especially hydrochloric acid. In consequence of the slight acidity of the gastric juice in the stomach of children, it cannot act as forcibly to retard fermentation as the same secretion in the adult.

(10) It has not yet been determined what significance certain micro-organisms have upon digestion.

(11) Functional disturbances in the stomach of children are due to changes in the quality and quantity of the gastric juice, the regular exchange in its ingredients being disturbed, or the parts being subjected to physical or chemical changes which are not yet understood.

(12) The quantity of gastric juice in the stomach of children may be lessened without necessarily causing an increase of lactic acid, or the appearance of acetic or butyric acids.

(13) When the normal secretion of the stomach is deficient, acids are developed which are not suitable for normal digestion.

(14) The presence of too much mucus in the stomach may paralyze the digestive activity of the gastric juice, though the latter may be normal as to quantity and as to composition.

(15) If too much food enters the stomach, or if it remains there too long, an insufficient quantity of gastric juice will be secreted for its digestion.

(16) The majority of gastric dyspepsias in children are caused by the deficiency of hydrochloric acid in the gastric juice. Functional disturbance is rarely caused by excessive secretion of gastric juice.

(17) Diseases of the stomach with definite anatomical peculiarities, manifest themselves by the presence of an abundance of mucus, serum and inflammatory elements. The severer the disease and the longer it lasts, the more conspicuous will be these elements.

(18) With inflammation of the gastric mucous membrane, digestion is reduced to a minimum, even if the gastric juice remains normal in quantity and quality.

(19) Disturbed digestion is accompanied by the appearance of an increased number of fermentation-phenomena, with the formation of acids foreign to the stomach and its work, as well as the breaking up of albumen and the formation of decomposition-products. The substances which are submitted to fermentation are the fats and the excess of mucus, which ordinarily do not undergo such changes.

(20) A diminution or failure in the presence of hydrochloric acid in the stomach, signifies the formation of pathogenic elements in the soil favorable to such development, the anti-microbial power of a sufficient quantity of hydrochloric acid being wanting.

(21) It is quite possible that certain forms of micro-organisms or their products, are responsible for the different diseases in the stomachs of children. The means for treating the abnormal condition of the stomach, which has been found extremely efficient in numberless cases, is irrigation.

THE ETIOLOGY OF ACUTE DIGESTIVE DISORDERS IN INFANTS.²

Investigation in Germany was first directed to the great mortality of infants during the summer months

² Seiffert: (*Jahrb. f. Kinderh.*, xxxii, 4); *Arch. Pediat.*, vol. viii, November, 1891.

by the published report in America concerning the "Summer Diseases of the Children of New York." Bedra also called attention to the fact that the contents of the intestines in infants who suffer from digestive disorders are similar to organic matter which has undergone fermentation or putrefaction, and that probably these diseases are due to processes of decomposition. At that time, however, the process of fermentation was not thoroughly understood. Eichstedt called attention to the similarity of the dyspeptic fecal evacuations of infants with fermenting substances. Attention was next called to the high atmospheric temperature and depression of the surface (ground) water during the months when summer complaint prevails.

These facts, together with the yearly occurrence of the disease in an epidemic form, rendered it possible that the vitalistic fermentation theory of Pasteur might throw light upon the pathology of the condition.

Then Baginsky showed that with the increase in the temperature the mortality among infants from diarrhoea increased, especially in neighborhoods where the hygiene of the home was bad. Thus the disease might arise from miasmatic influences proceeding from fermenting substances, or from direct decomposition of milk in consequence of the action of spores upon it.

Meissner agreed with Baginsky's view, especially observing that the disease occurred when children had been fed from dirty bottles, and that breast-fed children seldom suffered with it. Many other observations followed the foregoing, the opinion steadily gaining ground that the disease was due to fermentation.

Le Sage has divided the digestive disorders into the following classes:

(1) That in which the cause consists in fermentation of the contents of the stomach.

(2) The lienteric, which is due to deficient digestion of the milk.

(3) Diarrhoea, caused by reflex processes in teething and in taking cold.

(4) Infectious diseases of the intestines, which may be due to poisons resulting from the decomposition of the food by micro-organisms, or to general infection, with a specific parasitic bacillus, analogous to the process in cholera.

(5) A bilious green diarrhoea.

Escherich distinguishes three forms of digestive disorder caused by the use of decomposed milk:

(1) Isolated fermentation of the stomach, causing retching, acid vomiting and dilatation of the stomach.

(2) Acid diarrhoea, caused by fermentation in the large intestine, which is carried on without the presence of oxygen.

(3) A colitis with feculent diarrhoea, caused by fermentation in the large intestine.

Clinical experience, as shown in the successful treatment of gastric disorders by irrigation of the stomach, and the antiseptic treatment of the entire alimentary canal, force the conviction that these disorders which are under discussion are the result of decomposition processes, which are caused by bacterial agencies. Starting with the hypothesis that the contents of the alimentary canal are the substratum from which the intoxication which gives rise to gastrointestinal disease proceeds, the following questions are submitted:

(1) Do the contents of the stomach in dyspepsia in young children have a relatively greater quantity of

micro-organisms than the contents of the stomach of healthy children?

(2) Is there a relation which can be determined between the relative quantity of germs in the stomach of sick infants, and the intensity of the disease from which they are suffering?

(3) What are the relations between the relative quantity of germs in the contents of the stomach and the intensity of the disease on the one hand, and climatic factors, which influence the destruction of the milk, the factor of temperature particularly, on the other hand?

To answer the foregoing questions, a quantitative bacteriological analysis was necessary, of contents taken from the stomach of a living child.

Investigations of this character on an extensive scale were made by the author, and from these it was concluded that in the acute dyspepsias of infants one has to deal with spores, which are antagonistic to the acid of the contents of the stomach, are introduced with the nutriment, and develop luxuriantly at the temperature of the body. The phenomena of severe dyspepsias, and especially those of cholera infantum, are the phenomena of acute intoxication; hence, it is reasonable to seek for the cause of the disease in the poisons generated by the saprophytes of the contents of the stomach.

These diseases are most destructive at the time when high temperature, through the action of micro-organisms, works destructive changes in food-substances, and almost disappear when the weather becomes cool. There are also cases which have the character and etiology of general infectious diseases.

These diseases are not epidemic or endemic in the same sense as the continued fever, lacking the characteristic developments and history which such general infectious diseases have. For the further elucidation of the etiology of acute dyspepsia, the chemical changes which are caused in the milk by the bacteria found in the stomach, must be studied, especially by experiments upon animals. Subcutaneous or intravenous injections of the bacteria should be made upon suitable animals.

DILATATION OF THE STOMACH IN CHILDREN.⁸

The high mortality in infants and children from disorders of the digestive apparatus has long furnished a difficult problem in therapeutics to pediatricians, and the stomach is the organ which has demanded most earnest study. The therapeutic portion of the subject has been studied with especial earnestness since the French drew attention to the frequency with which dilatation of the stomach occurs in children.

Dilatation of the stomach may enlarge the organ regularly or irregularly. The hour-glass form is a common example of irregular dilatation. It must necessarily produce thinning of the walls of the stomach, and if the condition is prolonged, fatty degeneration and atrophy of the muscular elements of the stomach must take place. The mucosa is anaemic or hyperemic, according to the catarrhal condition which exists.

The causes of gastric dilatation are divided into two categories:

- (1) Those which are due to mechanical obstacles: (a) congenital stenosis of the pylorus; (b) overfeeding and overwork.

⁸ Henschel: Arch. f. Kinderch., xiii, 1 and 2; Arch. Ped., vol. viii, November, 1891.

(2) Those which result from muscular atony, and are caused by, (a) irregular conditions of the constitution; (b) abnormal fermentation in the stomach; this cause far exceeds all the others in frequency.

If dilatation is due to congenital stenosis of the pylorus, vomiting and pain will be present almost from the taking of the first food into the stomach; constipation and flatulence will also be present: anæmia, emaciation and death will soon follow. Those cases of gastric dilatation which arise from constitutional disorders or from overloading manifest themselves more slowly, occasional attacks of vomiting being present, then loss of appetite, until at length the smallest quantities of food are refused. The abdomen is swollen and the bowels are constipated, the tongue is coated, but the temperature remains normal. Occasional attacks of gastric catarrh further weaken the patient, who finally dies exhausted.

If dilatation is due to fermentation, the course is more rapid; gastric catarrh is a more prominent symptom, and with it are associated severe nervous symptoms, chills, depression of the eyeballs, apathy, convulsions, collapse, cyanosis, dyspœa. The most important symptom in making a diagnosis is, of course, the tympanic note, which is obtained by percussion. Another is the succession sound which is produced by the rolling about of the fluid in the stomach as the child is shaken from side to side; but this and other similar signs are not available; if the child is suffering with diarrhoea, the fluid will also roll about in the intestines. The prognosis of this condition depends very much upon the condition of the child in general. It is absolutely bad if there is stenosis of the pylorus. The danger of the situation is increased by the fact that the resisting power of the system is lessened as the child is unable to take nourishment. He becomes more susceptible to intercurrent diseases, and yields to them more readily than when digestion is intact.

One of the most useful means ever devised for the relief of gastric dilatation consists in the irrigation of the organ. The soft sound is safer to introduce into the stomach for an irrigating tube than the hard one. It must not be passed too low lest the end be so bent that the return flow of fluids would be prevented. One may use for irrigation, simply warm water or solutions of resorcin, benzoate of soda, or boric acid. If the dilatation is of long duration, irrigation may be required twice daily. As to diet, Epstein recommends for the first few days albumen water, black tea, oatmeal gruel and milk in small quantities and at frequent intervals. For nursing children, he advises to refrain from weaning as long as possible.

Prophylaxis is, however, the best treatment; it is easier to avoid producing gastric dilatation than to cure it when produced.

TYPHOID FEVER IN AN INFANT.⁴

Typhoid fever being an extremely rare disease in young children, the author has reported the present case at considerable length. The patient was a boy eight months of age, bottle-fed, small, thin, and delicate looking, but well until the onset of this attack. He was first seen on October 2d, the third day of the illness. The temperature was 102.5° F.; the pulse 140. Believing the case to be one of entero-colitis, castor-oil was given, and the diet carefully regulated.

⁴ England: Montreal Medical Journal, February, 1891; Archiv. Pediat., May, 1891.

During the next week the temperature ranged from 102.5° F., in the morning, to 104° F., in the evening, the remission usually beginning after midnight. The spleen became enlarged, and could be felt as a smooth, firm mass two inches below the ribs. The liver could also be felt an inch below the costal cartilage. An eruption soon appeared upon the abdomen, chest, and back, consisting of numerous small, isolated, bright rose-spots, about the size of a pin's head, or a little larger. The diagnosis of typhoid fever was based upon the appearance of the eruption, persistent high temperature, tympanitis, enlargement of liver and spleen, and gastro-intestinal derangement evinced by vomiting, pain, and looseness of the bowels.

During the second week, the temperature ranged from 102° to 103.5° F. Slight bronchitis developed, the eyes were sensitive to the light, and there was evidently pain in the head.

At the end of the third week the temperature had become intermittent, the morning temperature reaching normal on October 17th.

The diet was milk, rice-water, and raw-meat juice. The treatment was symptomatic. Twelve drops of brandy were given every two hours throughout, and tepid sponging and cold to the head were systematically carried out. A full dose of quinine was given if the afternoon temperature reached 103° F. No complications or sequelae followed, and the child made a good recovery.

THE OPERATIVE TREATMENT OF CHRONIC HYDROCEPHALUS.⁵

An operation for chronic hydrocephalus presents no technically insuperable difficulties; but it is important to consider in what cases it is allowable, and what will be obtained by the operation in favorable cases. The results of operations which have heretofore been made are not encouraging. Incision and drainage of the hydrocephalus sac have given no better results than earlier methods. The propriety of such operations might, therefore, be questioned. Of course, not every case of chronic hydrocephalus is suitable for operation. Every intracranial effusion of fluid of moderate extent must be let alone, also those cases of congenital hydrocephalus in which a rudimentary development of the brain is suspected, all these cases being complicated also with spina bifida or some other serious lesion.

Those cases are to be taken into consideration in which, in spite of hydrocephalus, the children are psychically and physically well developed, or at least were so until the enlargement of the cranium began. Such children should show a steady though slow deterioration as the result of cerebral irritation or pressure conditions. Any operative procedure will be the less dreaded in such cases when one realizes the gloomy prognosis without such a possible source of relief. Such children become weak-minded or idiotic. They do not learn to talk at all, or that which is learned is quickly lost. If the pressure conditions continue only a few cases are there which escape total blindness. In an advanced condition of hydrocephalus complicated movements of co-ordination are impossible; walking, standing and sitting may be impossible.

If such a child learns to walk, the gait is wavering and uncertain. Pauses, contractions, partial and general chronic spasms are ordinary occurrences. All

⁵ Jahrb. f. Kinderh., xxxi, 1 and 2; Archiv. Pediat., April, 1891.

these symptoms are more or less conditioned upon the accumulation of the ventricular fluid, and the increase of endocranial tension. The circulation in the cranial cavity is weakened by the pressure, is also retarded, and may be stopped. Thence will arise functional disturbances, and then pathological changes in the brain substance. If the pressure is removed by arrest of the secretion and ossification of the cranium, restoration to a certain extent is possible. Atrophy of the brain is present with most of those who recover, and they remain idiots for life.

In the case upon which the author operated, great improvement took place after each withdrawal of fluid. The comatose condition passed away, the pupils reacted to light, the pulse became fuller and stronger, the breathing regular, and the desire for nutriment returned. The entire condition of the patient was satisfactory until the appearance of pus-corpuscles in the cerebro-spinal fluid removed the hopes of success which had been raised. If suppuration could be avoided, the author thinks that incision and drainage are better treatment for such cases than any other method which has been proposed.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY.

JAMES J. MINOT, M.D., SECRETARY.

STATED Meeting, Saturday, October 31, 1891, Dr. E. N. WHITTIER in the chair.

DR. F. W. JOHNSON reported a case of

PREGNANCY AND LABOR AT FULL TERM FOLLOWING AN ALEXANDER-ADAMS OPERATION.¹

DR. E. M. BUCKINGHAM read a paper on

SOME OF THE USES OF THE STOMACH-TUBE.²

DR. T. A. DEBLOIS: I have had the pleasure of seeing Dr. Buckingham operate with the stomach-tube occasionally, and, of course, as regards the indications for the operation, no one doubts the usefulness of the stomach-tube in cases of chronic gastric catarrh. It is in regard to the use of the soft tube rather than the hard one I would like to speak. To me as an outsider looking at the operation, the swallowing of the soft tube was much like a young bird swallowing a large worm. The bird seemed to enjoy it, but the patient did not. I have used the stomach-tube a good deal in other gastric troubles. I carried one round for a year without having occasion to use it except for a case of poisoning, and then did not have it with me.

I came to use the stomach-tube to dilate strictures of the oesophagus, and I have found that small rectal bougies made excellent dilators of the oesophagus. I want to bring up one point, and that is the ease with which the stiff tube can be passed. If the head is pretty well back and the left hand on the epiglottis, you can pass it quickly and easily. I think the limber tube is slow to pass. Of course, after the tube is in, one tube is as good as another. Perhaps the stiff one is a little better, because it cannot be constricted by any spasm of the oesophagus.

DR. T. M. RORCH: The subject of stomach washing is an important one, and although it is one of the recog-

nized forms of treatment for chronic gastric catarrh and vomiting, it is not employed in this community to the extent that it is in other parts of the country. When I had charge of the City Hospital out-patients, I had a case which resembled the last one reported by Dr. Buckingham. A young man had for many years suffered from chronic gastric catarrh, with its attending symptoms, and was much relieved in a month or six weeks by the simple process of washing out the stomach with warm water.

We should also perhaps speak of the washing out of the stomach in general, for instance, at what ages you can begin. The stomach can be washed probably at any age without danger to the individual. DR. SEIBERT, of New York, performed the operation on his own child when it was but thirty-six hours old. The child was seized with obstinate vomiting, threatening its life, and one or two washings out with sterilized water stopped the vomiting.

The washing of the stomach in adults was done as long ago as 1869 or 1870, by Kussmaul. Stomach washing in children was begun some years later, about 1880, by Epstein of Prague; and considering the small number of cases in this community where the stomach has been washed by physicians, it is extraordinary to note the number of cases that have been so treated abroad. We here treat with drugs, and it is well known with what little success, in the vomiting of children and in the different forms of catarrh. I am not especially advocating at present the washing out of the stomach, but I do think it is well to bring to the notice of the Society the fact that we are a little too conservative about trying some of these methods for preventing what may lead to even death in young infants, and that we really have not given savage a fair trial.

DR. SEIBERT, of New York, has done a great deal of good work in this direction, as has DR. BOCKER, of Baltimore, at the Wilson Sanitarium; and certainly their reports show that it is a most efficient method for dealing with vomiting and with catarrhal conditions. At the same time I think we should recognize that it is not merely by washing out the stomach that we can effect a cure in these cases. Some physicians hold that all that is necessary is to distend the stomach with water and the catarrhal condition will pass away. That is a little shortsighted. We know that the water in all probability does not enter the small intestine, and that the duodenum may be the nidus where the disease lurks, so to speak, in these catarrhal conditions. Where we have obstinate cases of this class, we are right in saying that stomach washing is part of the treatment, and I know of very few cases where it has been followed by dangerous symptoms. The idea is that in these catarrhal conditions you cannot put a disinfectant in the stomach which will kill the germs. In the first place in all probability the disinfectant will not reach the whole of the stomach. The upper part of the greater curvature will not be reached by the medicines you give. The medicine is either absorbed or passes through the pylorus. If you wash out the stomach, you wash out what is in the folds of the stomach in all probability, and the curds which are formed and which keep up a catarrhal or dyspeptic condition will be removed. DR. JACOBI, of New York, has expressed an opinion of this kind, if I remember rightly, and DR. KOPLIK has reported a number of interesting cases.

The technique of the operation with young infants is the use of the soft catheter about nine inches long,

¹ To be published later.

² See page 28 of the Journal.

or you can increase the length of the catheter with a glass tube. It is said to be very easy to insert the catheter. We must be careful not to distend the stomach too forcibly. An infant's stomach is very easily distended; hence instead of using the fountain syringe we had perhaps better substitute the method, which Epstein originally used, and I believe, continues to use — a simple funnel attached to the catheter.

DR. G. LIEBMANN: The last two or three years I have had considerable experience with the stomach-tube, and especially in catarrh of the stomach. I must say that I think the effect of washing out in ordinary chronic catarrh of the stomach is not exactly what I anticipated. I find that I can bring about an improvement occasionally the first two or three times washing out the stomach, but then the improvement stops, and the results will not go on. I think in such cases the moral effect is as much as the absolute washing out. On the other hand, in dilatation of the stomach I think it is the supreme remedy. With regard to the introduction of the soft tube, I would state that some time ago I exhibited here a stilet or mandrin made of rattan, which I use continually in cases where the patients are nervous. I find I get along much better than before. It is not exactly new treatment. The men in Europe have been using it lately, especially Leube. It is a great adjuvant in the hands of the physician. Before I used this mandrin, I failed in some cases, having to depend on the co-operation of the patient. If he does not swallow, we cannot push the soft tube through the pharynx into the esophagus, and have to give up the passage. The use of the mandrin does away with this difficulty.

I think the greatest triumph of the stomach-tube lies not exactly in the therapy alone but in the diagnosis. If we use the old-fashioned methods of examination of the stomach alone, we are in the dark, whereas, if we examine the contents of the stomach, we know what we are about.

DR. CHARLES P. PUTNAM: I have used the stomach-pump for washing and feeding in a child about eight months old, and can testify to the great ease with which it is done and the good result of the treatment. Dr. Rotch has described the method. The child had been unable to retain food and was extremely restless, but after the washing, it slept for a long time, and after a time was able to retain food swallowed in the ordinary way.

DR. BUCKINGHAM: There is a use of the tube that has not been mentioned to-night. Some new-born babies are too weak either to take the breast or the bottle, or even to swallow. In a certain number of such cases a soft catheter has been introduced, and the child fed through this until it has gained strength.

With reference to the use of the tube being disagreeable, I certainly meant to dwell upon that and am glad to hear from Dr. DeBlois that the stiff tube is less objectionable in that respect. The soft tube, however, is introduced without the slightest trouble to the introducer, the trouble is all for the patient. I must take exception also to Dr. DeBlois's statement that the tube is got in entirely by means of the patient's swallowing. By gentle pressure it is easy to help him very much of course, if the tube was perfectly flexible this would not be true, but the tubes as made are not absolutely flexible because of the thickness of their walls.

DR. CHARLES P. PUTNAM: I once saw a case of diphtheritic paralysis where the child was being starved

to death because unable to swallow any food, and it was without the least difficulty that a large catheter was introduced and food given. The child recovered. The age at which it is said to be difficult is between two and the time when the child can be reasoned with. Up to two years it is easy to introduce the tube, and in the case I mention, it went in without any difficulty at all and without apparent discomfort.

DR. E. W. CUSHING presented a specimen of

DOUBLE PYOSALPINX.

with the following history. A young woman of twenty-three years, married one year, healthy until married, but soon after that time seized with pelvic inflammation, which frequently recurred.

Has been confined to bed for several months. Lately has been very ill and at last came under the care of Dr. Ruddick, who, recognizing the gravity of the case, at once called me in consultation, with reference to operation. On examination, the uterus was retroverted and held down by "adhesion." Bimanual examination showed tenderness on each side of uterus and indistinct masses high up on each side of pelvis. Bowels very constipated, partially owing to free use of opium (no motion for last two weeks). Patient was taken to Charity Club Hospital; bowels moved, opium stopped. Three days later, abdominal section. Omentum adherent; intestines glued together; large pus tube, with abscess sac as big as the fist, in place of ovary on each side, high up and crowding uterus backward; pus very foul. Removal; irrigation; drainage; satisfactory convalescence.

Dr. Cushing called attention to the danger of breaking up supposed "adhessions," which are thought to hold the uterus down, without knowing accurately what the condition is and what the manipulations are doing.

DR. HARE: I have here a cyst removed by Dr. Baker yesterday morning. It is a suppurating dermoid discharging through the bladder for three years. The woman noticed the enlargement about four years ago.

The following committee of five were elected by ballot, to prepare a list of candidates for officers of the Society: Dr. D. W. Cheever, Dr. F. Minot, Dr. F. W. Draper, Dr. T. M. Rotch, and Dr. Morton Prince. The secretaries of the various Sections of the Society were appointed by the President for the ensuing year.

THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

MEETING, November 14, 1891.

DR. G. H. WASHBURN reported, by invitation,

A CASE OF TUBAL PREGNANCY,¹

and showed specimen.

DR. F. B. HARRINGTON reported

A CASE OF TUBAL PREGNANCY,²

and showed specimen.

DR. EDWARD REYNOLDS reported

A CASE OF PROBABLE TUBAL PREGNANCY.³

DR. J. G. BLAKE said that it was strange that so few cases of extra-uterine pregnancy occurred in Bos-

¹ See page 30 of the Journal.

² See page 32 of the Journal.

³ See page 31 of the Journal.

ton, when one considers the large number that are reported from other cities, from Philadelphia, for example.

DR. C. P. STRONG said that in Dr. Harrington's case under ether, there was felt what seemed to be a dilated tube. If the patient had simply rested it is probable that the ovum, which was dead, would have been expelled into the uterus and she would have recovered without laparotomy, but being a working woman, she could not afford to keep quiet so long. This recovery, without laparotomy, is probably the history of a good many cases in places where many enthusiastic laparotomists are not to be found, and may explain the difference in the number of cases reported from different cities.

The cases of both Dr. Washburn and Dr. Reynolds suggested to his mind uteri bicornate. The histories would point to this rather than to tubal pregnancy, for in the latter form there would be more pain.

DR. REYNOLDS said that in his case he had made no definite diagnosis of tubal pregnancy.

DR. F. H. DAVENPORT said, in reply to a question of Dr. Reynolds, that he had detected no abnormality of the uterus, although he had examined the patient in the non-pregnant state.

DR. W. H. BAKER said that in former times cases like those reported would not have been recognized, for it was not known that the ovum could be extruded from the tube into the uterus.

Dr. Goodell, of Philadelphia, was one of the first to call attention to this point. He himself had seen one case where the ovum was expelled into the uterus, and the pregnancy went to full term.

In one case under his observation where haemorrhage occurred, the uterus was thoroughly curetted. The right side of the uterus was found enlarged at the time, but two weeks later, the flowing continuing, examination showed the uterus of normal size and filled with an ovum. There are many cases of extra-uterine pregnancy, however, where there are no marked symptoms until sudden pain and collapse occurs from rupture. In such cases one would not hesitate to open the abdomen at once. In one such case he operated, removed a basinful of clots and also the right tube, which was ruptured and bleeding. This case, unfortunately, died in eight or nine days. Cases suspected to be tubal pregnancies demand careful watching, and Dr. Baker believes that galvanism is most important. In two cases he had used galvanism in strong current, with good effect.

DR. WASHBURN said that four weeks after the expulsion of the ovum he had examined his patient and found an enlarged tube coming out of an enlarged horn of the uterus.

DR. HAVEN said that in a case operated on by him two years ago, and already reported to this Society, the severe pain was what demanded the operation, the characteristic pain of tubal pregnancy.

DR. GREEN said it is strange we see so few cases here in Boston compared with the number of cases reported elsewhere. He has particularly borne these cases in mind, and has never yet found a case, nor has he found that he has overlooked any. Some surgeons in Philadelphia have reported as many as six cases of tubal pregnancy in a year.

DR. BAKER said he had seen twelve cases in the past nine years.

DR. STRONG had seen four cases, and he believed

that it was generally possible to make a diagnosis from the symptoms. In one case, however, all the classical symptoms of extra-uterine pregnancy were present, namely, cessation of true menstruation with a bloody discharge, sudden severe pain and collapse. A mass was felt on the left side of the pelvis; she was operated on in the Massachusetts General Hospital, and a small ovarian tumor was found, and not, as was expected, a case of tubal pregnancy.

DR. KAAN spoke of a case which suggested tubal pregnancy, which in a short time became uterine, and wondered whether these cases were not often found and operated on at once — a fact which would account for the large number of cases reported by some operators.

DR. BLAKE reported some more

GYNECOLOGICAL CASES FROM THE BOSTON CITY HOSPITAL,

and showed specimens of fibroids.

DR. BAKER said he saw once in a while a subserous fibroid that departed from the usual custom, and gave pain by pressing either on the rectum or the bladder.

DR. HAVEN said that in one of his cases the distress from a small fibroid pressing on the bladder was so great that laparotomy was required.

DR. STRONG believed that removal of fibroids by laparotomy would be done more and more in the future, as it entails so much less danger than the operation of hysterectomy. He had recently removed a fibroid weighing six and one-half pounds.

DR. HARRINGTON said that the danger in the removal of large fibroids with thick pedicles was that of hemorrhage and shock, and he thought that curetting, even if it was required every few weeks, was preferable.

DR. BAKER showed specimens of cystic ovaries from a patient of twenty-eight years. She had suffered pain, painful micturition and constipation. On opening one of the cysts a bloody fluid poured out, and the patient became collapsed, but promptly recovered on flushing the abdomen with warm water. The same thing occurred in opening the other ovary, and it seemed as if the patient would die, but flushing with warm water again revived her, and the patient is now doing perfectly well. He wondered whether the collapse could have been due to the irritating effect of the fluid in the peritoneal cavity.

DR. REYNOLDS suggested that the sudden relief of the tension in the ovaries might have caused the collapse.

DR. HARRINGTON did not think that either explanation was the correct one, or it would have been seen in other cases.

THE NEW YORK ACADEMY OF MEDICINE. SECTION ON GENERAL MEDICINE.

STATED Meeting, December 15, 1891, FRANCIS DELAFIELD, M.D., chairman.

DR. H. P. LOOMIS read a paper entitled

A STUDY OF THE PROCESSES WHICH RESULTS IN THE ARREST OR CURE OF PULMONARY PHthisis.

He stated that he had made a series of observations extending over the past two years for the purpose of determining the following points:

(1) In what proportion of cases met with on the autopsy table are found the evidences of cured pulmonary tuberculosis?

(2) What are the gross and microscopical appearances presented by the lungs in these cases, and by what histological changes was the cure effected?

(3) After the lungs are healed, are tubercle still present in them?

(4) How often are the evidences of localized or general adhesive pleurisy found, and what effect have such pleuritic changes had on the pulmonary structure?

Of 1,146 autopsies at Bellevue Hospital, 383 were made on persons who either died from tuberculosis or showed in their organs an active or chronic tubercular process. In the other 763 autopsies made on non-tubercular subjects, 276, or 36 per cent., showed lungs which were bound by organized adhesions, either general or local, to the chest wall; these organs being otherwise free from disease, 71, or over nine per cent., presented changes in the lung which he regarded as characteristic of healed pulmonary tuberculosis.

The post-mortem appearances in cases which might be regarded as cured, necessarily varied with the extent of the tuberculosis and the stage to which it had advanced before its arrest. On the basis of their gross appearances he grouped his cases under the following heads:

(1) That class in which the apex of the lung is found adherent to the costal pleura, with a puckered and depressed condition of its surface. Sixty of the 71 cases mentioned showed this condition. On cutting into the lung one or more dense fibro-cartilaginous nodules, varying in size from a cherry to a walnut, were seen beneath the depressed surface, or, if they were situated in the central portion of the upper lobe, they were generally connected with the surface by easily recognizable, dense bands of new connective tissue. In the centre of these nodules a chalky mass was often found, and this was frequently studded with sharp spiculae as hard as bone. In a few cases the indurated portions of the lungs were not nodular, but diffuse and connected with the pleura. Connected with the thickened pleura were white septa running through the lungs, composed of a condensed cellular substance intermingled with fibrous tissue. Often all traces of alveoli had disappeared.

(2) Healed cavities. Six of the cases showed this condition, and they divided themselves into two forms: (a) Where the cavity was empty and communicated with a bronchus; the cavity being situated in the central portion of the lung, closed on all sides, and lined with a thick, dense fibrous or fibro-cartilaginous membrane sometimes half an inch in thickness. (b) Where the cavity was contracted to such an extent by the growth of fibrous tissue (often over an inch in thickness) that it was almost obliterated, and appeared as a linear cicatrix. The adjoining pulmonary tissue was generally found to be the seat of emphysema and to contain patches of interstitial pneumonia. These internal cicatrices were almost always accompanied by puckering of the corresponding surface of the lung with depression of the chest wall.

(3) Two cases came under his observation in which there had been a complete transformation of the whole of an upper lobe into a compact, homogeneous mass of fibrous tissue, without a vestige of pulmonary substance being left.

An examination of microscopical sections presenting the evidences of arrested and healed tubercular processes led Dr. Loomis to the following conclusions:

All fibrous developments result in induration, but it is not easy to determine how or why the tubercular processes were arrested, or how the final result is brought about. At the edge of the pulmonary tissue destroyed by the tubercular process, in many sections, new connective tissue could be seen just forming. This seemed to be derived from three sources:

(1) The intralobular connective tissue had been infiltrated with round cells which were being changed into new connective tissue cells. In some the intralobular septa had been increased ten-fold, and presented an effective barrier to the advance of the tubercular process. The new connective tissue was highly vascularized.

(2) New connective tissue was seen forming in the alveolar walls.

(3) The connective tissue around the vessels and bronchi had become greatly increased. The latter were often almost obliterated by the contractions of the new connective tissue, but the lumen of the pulmonary vessels was but slightly interfered with.

In some sections adhesions of the pleura seemed to be the first step in the development of new connective tissue in the lung substance, and the new fibrous tissues from the pleura and the intralobular septa offered, he thought, a dense barrier to the advance of the tuberculosis, while the incipient softening was not attended, as is usual, by the continued deposition of tubercle. The new connective tissue, by its contractions, encapsulated the tubercular area, compressed and rendered inert the cheesy masses, and limited the advance of cavities, reduced them in size, and finally caused them to cicatrize and entirely disappear. One fact especially impressed him, and that was the hyperemic condition of the tissue surrounding the tubercular areas, where the same connective tissue was forming. Throughout the fibrous tissue new capillary vessels were everywhere seen. An unobstructed circulation and an intense hyperemia were conditions so constantly present where recent fibroid processes were active, that they seemed to be essential to the cure of phthisis.

From fifteen lungs showing the characteristic lesions of healed phthisis, a number of microscopical sections were cut, and these were stained for tubercle bacilli; but in none were any bacilli found.

Inoculation experiments were conducted upon rabbits with the object of ascertaining whether the circumscribed fibrous nodules containing chalky or cheesy deposits, and found generally at the apex of the lungs, contained tubercle bacilli. The settlement of this point, he thought, was important, as this was the only means we had of determining whether phthisis is ever absolutely cured. Even a few bacilli remaining in an apparently healed area must of necessity always be a source of danger to the individual. These inoculation experiments showed that while in the majority of cases no tubercle bacilli could be demonstrated in the healed pulmonary areas, still the fact that they are found in certain instances where the disease had remained latent for an indefinite period, while the nodules presented the same appearance as in the other cases, emphasized the difficulty of determining just when all dangers from all phthisical processes have ceased. Dr. Loomis thought that we might here, perhaps, have an explanation of the sudden de-

velopment of phthisis in those cases where a localized and perhaps forgotten tuberculosis from which apparent recovery has been made, suddenly redevelops.

In giving his conclusions, he said his microscopical examinations seemed to establish that fibrosis is the only method by which tuberculosis of the lungs can be recovered from. The gross description of the lungs which he had given he said was the natural grouping of those which had come under his observation. There was one suggestive fact discovered in his examinations, namely, that whenever the nodular mass or masses presenting the anatomical characteristics of healed phthisis were situated in the substance of a lobe, one or more broad and easily recognized bands of new connective tissue passed from the nodule to the pleura through the apparently healthy pulmonary tissue. At the place where the bands reached the surface of the lung evidences of a localized pleurisy were found, generally with adhesion of the two surfaces of the pleura. The appearance of these bands, so often repeated, suggested that some constant and determinable influences were at work, and he believed that in the study of the lymphatics and the distribution of pigment in the lungs, rested the explanation of their presence.

His examination of the lungs of cured phthisis convinced him that it is not the tubercle which undergoes evolution, but the normal connective tissues of the lungs which surrounds it, and of this connective tissue, it is the interlobular, assisted by that of the pleura, which first increases and is able to resist the advance of the destructive processes. If by any means the vessels in this tissue could be kept open and the capillaries filled with blood, fibrous processes would be established as the result of the irritation and the active congestion. If there was any virtue in Koch's tuberculin, high elevation, or certain indirect methods such as the pneumatic cabinet, might it not be due to the localized congestion which they excited? A microscopic examination of the lungs removed from three patients who had been treated for a long time by injections of Koch's tuberculin, showed a most intense active hyperemia of all the vessels in and around the old fibroid areas at the apex of the lungs, while in these situations an unusual formation of new connective tissue was taking place. When once formed the fibrous growth acted as a bulwark to prevent the extension of the tubercle bacillus. In this way such tuberculous exudation as had occurred would be rendered abortive, and even large ulcerations would be healed and cicatrized by the newly-formed connective tissue. It was a well-known pathological fact that loss of the parenchymatous elements of a tissue or organ is followed by a new growth of connective tissue to take their place. It was necessary that the new growth should be pathological in intensity to be effective where there was much destruction of tissue.

Might not this rule be applied to the lungs to explain the conservative changes which take place in them? In phthisis the pulmonary parenchyma, being of a higher grade of vitality than the connective tissue, is acted upon and destroyed first by the tubercle bacilli. The surrounding connective tissue is stimulated to increased activity by the irritation which is produced, just as occurs in other places in the body, on the application of an irritant. Again, the parenchyma of the lungs being destroyed, the connective tissues must increase to fill the vacancy produced.

DR. J. WEST ROOSEVELT said that from a clinical standpoint it was very important to remember that healed phthisis is not (clinically speaking) phthisis. It was not the kind of phthisis which came under our notice in practice. Doubtless we all saw cases of phthisis which we did not diagnose, and there was no reason why we should do so. In incipient phthisis it was well-known how very difficult it often was to make a diagnosis, and there were in all probability many cases of phthisis which recovered without coming under the physician's care at all.

Dr. Loomis had referred to the great frequency with which pleuritic adhesions were found in the cases examined by him after death (36 per cent.). Clinically, nothing like this percentage was noticed. He hoped that the Doctor would succeed in throwing some light on the dark subject of the lymphatics of the lung, as hitherto it had seemed utterly hopeless to try to understand the pulmonary lymph currents. He did not understand why Dr. Loomis held that pleuritic fibrous adhesions should be considered as secondary to phthisis. It seemed to him that they were merely a part of the phthisical process.

The Chairman, DR. DELAFIELD, said that in his paper Dr. Loomis had given an exact and complete description of the conditions which any one accustomed to making autopsies constantly meets with. For some time he had believed that the reasons for the apparent discrepancies which so often exist between the clinical history and the post-mortem appearances was this, that we have got so much in the habit of regarding all tuberculous inflammations as very serious, if not absolutely fatal, whereas, it was unquestionably true that a tuberculous inflammation, if it occupied only a small area in the body, could be a very little matter; provided it remained confined to a small part. He was convinced that a large number of persons have a very small tuberculous inflammation of a small part of the lung which never even makes them sick. The inflammation runs its course, and they recover from it. Afterwards, when they die from some other cause, the evidences of the previous tuberculous trouble are found at the autopsy.

When larger areas were involved, the inflammation might run its course also, but so much of the lung would have been implicated that such persons could hardly be called very healthy. There would be no longer an active inflammatory process, but the lung would always remain more or less damaged.

As regards the healing of tuberculous lungs by the formation of fibrous tissue, this was a question of very great importance. The presence in the lung of tubercle bacilli was of itself of no consequence. But the bacilli were of consequence when they had excited an inflammatory process. This process either went on to death or underwent healing. These things might happen:

(1) We may have a simple exudative inflammation, with the formation of its characteristic products; and all this exudation may be absorbed and disappear from the lung.

(2) We may have the formation of new connective tissue; and such tissue has very little tendency to disappear. On the other hand, it has a tendency to become changed into a denser connective tissue.

This did not seem to him to be a barrier to further tuberculous trouble, as Dr. Loomis had contended. The only thing that could happen was that it could be

changed to new connective tissue, and it was not, in his opinion, a source of protection against tuberculosis. The paper was a genuine "dead house paper," and it contained an accurate description of a very real thing. The only question was as to how that real thing was to be interpreted.

Recent Literature.

A Practical Treatise on the Diseases of Women. By T. GAILLARD THOMAS, M.D. Sixth edition. Enlarged and thoroughly revised by PAUL F. MUNDÉ, M.D. Philadelphia: Lea Brothers & Co. 1891.

The profession has sadly felt the want of a text-book on the diseases of women, which should be comprehensive, and at the same time not diffuse, systematically arranged so as to be easily grasped by the student of limited experience, and which should embrace the wonderful advances which have been made within the last two decades. Fifteen or twenty years ago, Thomas's work fulfilled these conditions, and the announcement that a new edition was about to be issued, revised by so competent a writer as Dr. Mundé, was hailed with delight.

The examination of the work does not in the main disappoint the expectations which were entertained. Dr. Mundé brings to his work a most practical knowledge of the subjects of which he treats, and an exceptional acquaintance with the world's literature of this important branch of medicine. The result is, what is perhaps on the whole, the best practical treatise on the subject in the English language. The original work is preserved as a basis, but amplified and enriched with the results of modern research. Much has been interspersed with the old material, and several new chapters added.

The difficulties inherent in the task of revising another man's work have been in the main successfully overcome. The only criticism we have to make is that in the new form it has, perhaps, lost a little of its value as a text-book. A text-book on any subject should be simple, definite and not too diffuse.

Where differences of opinion have arisen between the author and the revisor, both views have been fully stated. That adds to the value of the book as one of reference for practitioners who are competent to decide between conflicting claims, but may be of disadvantage to the student who should be taught definite facts and opinions.

In spite, however, of this possible objection, it is, as we have said, the best text-book we know, and will be of especial value to the general practitioner as well as to the specialist.

The illustrations are very satisfactory. Many of them are new, and are particularly clear and attractive. The book will undoubtedly meet with a favorable reception from the profession.

The Comparative Anatomy of the Domesticated Animals. By A. CHAUVEAU, M.D., LLD. Revised and enlarged, with the Co-operation of S. ARLOING. Second English Edition, translated and edited by GEORGE FLEMING, C.B., LLD., etc. With 585 illustrations. New York: D. Appleton & Co. 1891.

It is some eighteen years since we reviewed the first English edition of this classical work. We are told

in the preface of the volume before us that it has since been several times reprinted. The present edition is a translation of the last French one, which appeared in 1890. The work is a very valuable one. The anatomy of the horse is the basis of the book, but there are frequent comparisons, not only with the structure of man, but with that of other animals. The list of these has been increased, the anatomy of the ass, mule, camel, and rabbit having been added. Moreover, recent progress has been noted. The section on the brain is much enlarged. We cannot give it unqualified praise, for we do not believe that the interpretation of the convolutions would be accepted as satisfactory by the best cerebral anatomists. We find nothing about cerebral localization, nor any hint at the relation between the formation of the brain and the peculiarities of faculties in different animals. In spite of shortcomings of this kind, we are very glad to welcome this new edition of an old friend.

T. D.

The Diagnosis and Treatment of Extra-Uterine Pregnancy. By JOHN STRAHAN, M.D., etc. 8vo, pp. 125. Philadelphia: P. Blakiston, Son & Co. 1889.

This is the Jenks Prize Essay of the College of Physicians of Philadelphia for the year 1889, the first award under the deed of trust. It is an essay of remarkable excellence. The style is clear; the difficulties of accurate diagnosis are carefully considered; and the treatment is systematically laid down for the various phases in which extra-uterine gestation presents itself. It is a scholarly work and will prove eminently useful to all who seek to fit themselves to deal with this most important and difficult subject in obstetric surgery.

A Treatise on Practical Anatomy for Students of Anatomy and Surgery. By HENRY C. BENNING, M.D., Lecturer on Anatomy and Surgery in the Philadelphia School of Anatomy, etc. Illustrated with 198 wood-engravings. Philadelphia and London: F. A. Davis, Publisher. 1891.

It is hard to guess what need this work was expected to fill. In parts it is no better than a compendium, and in others it gives glimpses of real merit. As a whole it is quite unsatisfactory. It certainly cannot pretend to rank as a first-class anatomy. It cannot take the place of any of the great text-books. On the other hand it does not have enough merits of its own to make it a valuable adjunct to them.

The Medical News Visiting List for 1892. Philadelphia: Lea Bros. & Co.

This is a very well-known visiting list. The present edition exhibits all the good points of its predecessors, besides having been revised and, where that was possible, improved.

LA GRIPPE. — "Well, Dennis," said the judge, "so you've had the grip. Heard you had a bad time?" — "Tis a terrible disease, sir, sure enough," said Dennis, "I thought I would never get over it. Sure I was sick fifteen days after I got well, sir!"

It is estimated that getting born costs the people of the United States \$250,000,000 annually; getting married, \$300,000,000, and getting buried, \$75,000,000. To the economical mind these figures will at once suggest the most advantageous course of conduct.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JANUARY 14, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE PRESENT INFLUENZA EPIDEMIC.

THE reports intimate that the present influenza epidemic has been quite as widespread and quite as disastrous as in the two previous years. Indeed in some localities in New England the epidemic has been even more severe and fatal than during the winter seasons of 1890 and 1891.

Three principal types, as usual, have been prevalent, the thoracic, the gastro-intestinal and the nervous, with a very decided predominance of thoracic cases. Indeed, in the majority of instances the physician finds his patient suffering from an attack of acute bronchial catarrh. The fever, however, runs higher, the cough and respiratory distress are somewhat more severe, the symptoms of general prostration are greater, and convalescence is much more tedious than in ordinary bronchitis. It has been remarked that what especially differentiates the "grippal" from common bronchitis is the prostration of the forces. This renders the administration of stimulants from the earliest stages necessary, and explains the unfavorable effect which frequently attends the use of antimonials and even veratrum viride.

Another peculiarity of the disease is the proneness which the catarrhal inflammation manifests to spread to the capillary bronchi, and even to invade the lungs, not merely isolated lobules, but whole lobes. It is only in a comparatively small number of cases that the influenza is pneumonic from the onset. After several days of attendance, during which only the signs of general bronchitis are present, the physician, expecting defervescence, is surprised at his morning or evening visit to find a decided increase of the fever (103° to 105° F.) and bronchial breathing and bronchophony at the base of one of the lungs. The cough previously loose becomes dry, paroxysmal, hacking and painful; when expectoration is established, the sputa are nummulated, purulent and may be streaked with blood. Here an examination of the sputum will often reveal the lanceolated micrococcus; true pneumonia

has implanted itself on soil prepared by the influenza. It is needless to say that it is in the careless, the feeble and the aged that this complication or sequel of the influenza is generally seen. Naturally the supervention of pneumonia causes no little alarm, but, dangerous as it may be, a considerable proportion of cases so affected recover. After a stationary period of a few days, the area of consolidation steadily diminishes, and convalescence is established.

But in a certain percentage of patients the pneumonia is primary instead of secondary. This form differs somewhat from that of ordinary pneumonia, and from their experience during the present epidemic many practitioners in New England will recognize the description of "grippal pneumonia, *d'embée*," given by a foreign contemporary: "The initial chill is wanting; the pain in the side is generally of little intensity; the fine, dry crepitant of frank pneumonia is rarely heard, but instead the sub-crepitant rale; the souffle is less rude than in the common form; the sputa viscous and little, if at all, streaked with blood differ scarcely from those of simple bronchitis. In general, the dyspnoea is intense and out of proportion to the extent of the phlegmasia; the pulse is of average frequency, is soft and without resistance. Some patients are delirious and have subultus tendinum; all are prostrated as in grave fevers. These pneumonias often pass to suppuration and are complicated with albuminuria, with meningitis, with endocarditis. They may also terminate in gangrene."¹

In a patient that is old and cachectic, the pneumonic inflammation may not pass beyond the stage of intense congestion. The patient dies in a few hours asphyxiated and in cardiac astyole. Of course, when the heart is fatty or feeble from other causes, as uncompensated valvular disease, the probabilities of rather speedy death from congestion, capillary bronchitis, pneumonic consolidation, etc., are preponderant.

It is to be understood that in the present, as in previous epidemics, the majority of cases are hardly more serious than if a given number of persons were simultaneously afflicted with a severe cold; the prostration following these mild cases is however considerable.

Every physician in general practice has had a few cases in which the nervous symptoms predominated. There is a violent headache comparable to migraine; this is an early and obstinate symptom. The patients have a sensation of constriction in the forehead and temple, and they often refer their pains to the back part of the orbits. There are also severe pains in the back and limbs with fatigue, depression, restlessness and insomnia. The rachialgia and feebleness of the limbs, the shooting pains in the members and joints have been (plausibly) referred to a localization of the virus of influenza in the spinal medulla. Sometimes the multiple neuralgias and the excessive enfeeblement of the limbs attending the attack bear a marked resemblance to the so-called infectious polyneuritis, and it is a sufficient fact in this connection that certain authori-

¹ Ferdinand Widal.

ties (as Remak) have described a polyneuritis (quite typical) of "grippal" origin.

We believe that fewer cases of the gastro-intestinal form of influenza have occurred in this epidemic than in the previous epidemics, yet instances are sufficiently common where, along with predominant manifestations on the part of the respiratory or nervous symptoms, there has been marked disturbance of the digestive organs, as shown by furred tongue and anorexia, nausea, vomiting, pain or a sensation of weight and oppression in the stomach, constipation or diarrhoea, etc.

Pervading diseases (as cardiac, nephritic diseases, pulmonary tuberculosis) have been provoked to unwanted aggravation by the epidemic influenza, and the mortality from these diseases has been greatly enhanced.

There are already some indications that the epidemic is on the wane. The overworked members of the medical fraternity in all parts of the country will welcome some material lightening of their burdens. Not a few physicians have averaged from twenty-five to forty calls a day all through this busy season.

THE ANNUAL REPORT OF THE NEW YORK COUNTY VISITING COMMITTEE OF THE STATE CHARITIES' AID ASSOCIATION.

The Nineteenth Annual Report of the New York County Visiting Committee of the State Charities' Aid Association for Bellevue Hospital and the Public Institutions of the city, states that during the past year few changes were made in the institutions. Chief among them was the appointment of a trained supervising nurse for the Almshouse and Workhouse Female Hospitals, and the adoption of a system of probation for the nurses under her. It has thus become the acknowledged policy of the Department of Charities and Correction that all the sick under its charge should have trained care, although as yet the male patients fare less well in this respect than the women. Among the other improvements referred to are wards for women under arrest, nearly finished at Bellevue Hospital; the new pavilion for "waiting women," at the Maternity Hospital on Blackwell's Island, and the near completion of a new brick pavilion at the Female Insane Asylum.

During the winter and spring, Bellevue Hospital was overcrowded, and because of the large number of acute cases the work of the nurses was very heavy. The wards are declared to have been in very good order throughout the year, although those under the care of the Mills' Training-school for male nurses, were, as usual, not so neatly kept as those cared for by the female nurses. The food is said to have been good and abundant, and the laundry-work better done than formerly. Much complaint is made of the condition of the City Morgue, which is contiguous to Bellevue, and a removal is urged. The report of the alcoholic ward shows that the number of patients admitted during the year was 2,753 males, and 1,100

females, an increase of 96 in the number of women, and a decrease of 129 in the number of men. These wards were much crowded during the year, and all sorts of makeshifts were used to accommodate the patients.

In regard to the Bellevue Training-school for Nurses, the following statistics are given: During the year there were 1,375 applicants for admission to the school, from which the 30 who were admitted were carefully selected. A class of 20 graduated. There were 1,215 calls for nurses, 26 of them being to fill positions in hospitals. Of these, 12 of the most important were supplied; but only a very small proportion of the calls for private nursing could be filled from graduates of the school. The report closes with a number of recommendations, among the most important of which is one for better accommodation for the city's insane through the enlargement of the settlement at Islip and the erection of decent and substantial buildings in place of the wretched pavilions on Blackwell's Island.

THE DREXEL INSTITUTE.

The Drexel Institute was lately dedicated in Philadelphia. The buildings and grounds have cost half a million dollars, and it has an endowment producing an income of \$50,000 annually. There is the beginning of a library. These are the gifts of Mr. Anthony J. Drexel. In addition, Mr. G. W. Childs has presented a famous collection of rare prints, manuscripts, relics and autographs. There is a system of free scholarships, but admission, as a rule, is to be gained by a small fee.

The training to be given is designed to keep in mind practical results, and the diploma is expected to secure for the young man or young woman graduating, a remunerative position in the actual every-day work of the daily life of the busy world.

There is to be a course of study and practice in art; a scientific department, with laboratories; a department of mechanic arts; a technical department. The provision for all this is most generous, and the aims so admirable — although not unique — that they call forth the best wishes of those wishing well to humanity, wherever they may dwell.

We confess, however, as humanitarians and hygienists and as advocates of preventive medicine, our enthusiasm is most aroused by the announcement that there is to be a department of domestic economy, which will be thoroughly practical. It almost makes us wish that we had been born later and born in Philadelphia. If it fulfils its purposes there will be no longer any excuse for celibacy. The course will extend over two years, girls and young women will be taught cooking in a model kitchen, and meals will be spread in a model dining-room. Will they, upon graduation, refuse to cook except in model kitchens, or to spread meals except in model dining-rooms? Probably they will, but it will matter less, for, in ad-

dition, they *may* learn millinery, dress-making, the building, sanitation, decoration and management of the house, household economy, human physiology and hygiene, business forms and accounts, free-hand drawing and elementary economies.

Our heart goes out to this Institute and its founder, and especially to its department of domestic economy. To the graduates of this department we should like to extend freely the right of suffrage — with a proviso that their interests in domestic economy should not thereby be curtailed; and also the right hand of fellowship at the hymeneal altar.

MEDICAL NOTES.

THE DUKE OF CLARENCE. — It is reported that the Duke of Clarence, eldest son of the Prince of Wales, is seriously ill at Sandringham. He is suffering from a severe attack of influenza, complicated with pneumonia.

YELLOW FEVER. — Recent reports from Brazil indicate that the epidemic of yellow fever shows little or no signs of abating at Santos. At Rio Janeiro, the conditions are much better. Yellow fever is reported in the Island of Jamaica.

THE INFLUENZA, although disappearing in some localities which were early attacked, has recently broken out in a severe form in several cities and towns both in this country and in Europe. In some cases the localities now going through the height of the epidemic are in the vicinity of those which suffered severely some weeks ago.

THE INFLUENZA IN BERLIN. — At a meeting of the Berlin Society for Internal Medicine, held in December, the present epidemic was discussed. The first cases were observed early in November. Observations point to the probability that the disease clings to a locality without excluding the possibility of transmission from one person to another. The present epidemic was marked by severe complications, especially in those who were already suffering from organic lesions of the heart, lungs or kidneys, or who were over forty years of age. Recurrences in the same person are not frequent and are generally mild in their course.

THE AMERICAN JOURNAL OF OBSTETRICS. — Dr. Paul F. Mundé has retired from the editorial management of the journal, a position which he has occupied for eighteen years. It will hereafter be edited by Dr. Brooks H. Wells.

ANNALS OF OPHTHALMOLOGY AND OTOTOLOGY. — Under the above title a new quarterly journal appears this month for the first time. It will contain original articles and reviews of current literature connected with the title-subjects, and also with rhinology and laryngology. It is published in Kansas City, under the editorial management of Dr. James P. Parker.

THE MEDICAL SECRETARY OF PUBLIC HEALTH. — In accordance with a resolution passed by the American Medical Association at its last meeting, the committee appointed for the purpose have submitted a petition to Congress setting forth the usefulness of the medical profession and praying for the establishment of a Medical Secretary of Public Health, who shall be a cabinet officer, and whose department shall take charge of all matters connected with disease and preventive medicine.

THE MARINE-HOSPITAL SERVICE. — The President has nominated Dr. Walter W. Wyman supervising surgeon-general. Dr. Wyman had been temporarily appointed to this position during the recess of Congress. Dr. John B. Hamilton, formerly supervising surgeon-general, who resigned to accept a position in Rush Medical College, in Chicago, has been appointed surgeon.

THE HEALTH OF FLORENCE. — Sir Douglas Galton has just issued a report with regard to the sanitary condition of Florence. During the last year out of 185,000 inhabitants there were 137 deaths from typhoid. The death-rate of the city, which twenty years ago was 36 per thousand has been reduced to 25, which was last year's rate. He thinks that by a thorough revision of the drainage system, Florence can be made one of the most healthy cities of Europe.

Poisonous American Apples. — The *Horticultural Times* of London has demanded of the Board of Trade that the importation of American apples be forbidden, because apple trees in America are sprayed with Paris green, to protect the fruit against the codling moth. It has been shown, however, that but one pound of Paris green is used to one hundred and fifty gallons of water, and that the spraying is done while the apples are very small, and that the amount of poison which could possibly remain on ripe apples is practically nothing.

AMERICAN HOG PRODUCTS IN FRANCE. — According to the new Custom House Law, American ham and bacon can be imported into France through the ports of Dunkirk, Havre, Bordeaux and Marseilles, where consignments will be examined by experts whose services will be paid for by the importer. These experts are to be appointed by the Minister of Agriculture. No American meat will be allowed to pass the Custom House unless it has been examined and certified as sound by the inspectors in question.

THE DEPOPULATION OF FRANCE. — During the year 1890, there were 38,000 more deaths than births reported in France. This very large diminution was in part, due to the influenza. It has been computed that the time required to double the population, according to the rate of increase of the last year, is in England 53 years; in Germany 77 years; in Russia and Italy 99 years; in Austria 139 years; and in France 230 years. In France, not only are there fewer marriages, but the age at which marriages take place has advanced so that now the mean age for men is about thirty years

and for women twenty-five years. The average number of children is three.

PHYSICIANS FOR JEWISH COLONIES.—An advertisement appears in the German journals asking for volunteers among Jewish physicians to take charge of medical affairs in the Jewish colonies which have been established in South America. Applicants must sign a contract for three years' service, they must speak German and have had hospital experience. Those who can speak the Russian Polish dialect are preferred.

BOSTON AND NEW ENGLAND.

THE WILL OF DR. BUCKMINSTER BROWN.—By the will of the late Dr. Brown, Harvard College will ultimately receive \$40,000, to found a professorship of orthopedic surgery, to be called the "Dr. Buckminster Brown Professorship." The books of the testator, relating to orthopedic surgery are given to Harvard College, the remainder of his medical works are given to the Boston Medical Library Association.

MEICAL INSPECTION OF THE BOSTON PUBLIC SCHOOLS.—It was expected that the plan of the Board of Health, to establish medical inspection in the public schools, would go into effect the first of the year, but by a rule governing the use of the special appropriation of \$5,000 made for this purpose by the last Common Council, most of the money has already been used for other purposes, and it has been thought advisable to wait until the present city government makes a new appropriation before putting the plan into operation.

MORTALITY OF BOSTON FOR THE WEEK.—The total number of deaths last week was the highest since the week ending January 11, 1890, when the last influenza epidemic reached its height. The deaths reported as due to influenza last week were twelve uncomplicated, and 32 associated with other diseases. The deaths reported to the Board of Health for the week were 339, making the death-rate 38.2. Of this number the deaths from consumption were 39, pneumonia 79, heart-disease 30, bronchitis 38. The number who died over sixty years of age was 116.

DEATHS IN BOSTON IN 1891.—The total number of deaths in Boston last year was 10,571, against 10,181 in 1890. The annual death-rate was 23.02 per thousand, while in 1890 it was 22.70, and in 1889 it was 24. The percentage of deaths from zymotic diseases to total mortality of 1891 was 15.27, which is lower than ever before in the history of the Board of Health. Consumption caused 1,352 deaths last year, which is less by 143 than in 1890. Pneumonia 1,149, as against 1,093 in the preceding year. Bronchitis 551, as against 453 in 1890. This increase is largely due to the influenza in December. Cholera infantum caused 597 deaths in 1891, 498 in 1890. The deaths from diphtheria were 232, which is small in comparison with 401, the number in 1890. The months of July and December had a greater number of deaths than any of the other months of the year; the record for July being 1,005, and that for December 1,133.

THE DEATH-RATE OF LYNN.—During the last year, there were 965 deaths in Lynn, a death-rate of about sixteen and a half per thousand. This is the lowest rate recorded in the city for several years. During December seventeen deaths were reported as due to influenza.

MASSACHUSETTS LEGISLATURE.—The joint standing committees on drainage, charitable institutions and public health are as follows: *Drainage*—(Senate) Clark, Franklin; Drury, Middlesex; Eaton, Norfolk. (House) Lane, Boston; Low, Brockton; Fiske, Ashland; Hale, Framingham; Dodge, Natick; Dole, Newburyport; Breen, Boston; Quian, Boston. *Public Charitable Institutions*—(Senate) Meade, Essex; Reade, Suffolk; Nutter, Plymouth. (House) Blanchard, Boston; Sawyer, Danvers; Clark, Palmer; Bicknell, Plymouth; Savage, Lowell; Fletcher, Belmont; Gay, Northampton; Head, Pepperell. *Public Health*—(Senate) Nichols, Worcester; Merritt, Hampden. (House) Blodgett, West Brookfield; Chance, Boston; Carter, Williamsburg; Dodge, Natick; Larkin, Tolland; French, Gloucester; Casey, Boston.

TUBERCULOSIS OF CATTLE IN NEWSHAMPSHIRE.—The board of commissioners appointed by the last legislature to exterminate contagious and infectious diseases among cattle have made a report to the governor. They have condemned 111 animals infected with tuberculosis. In several instances the disease was traced to herds of cattle brought from Massachusetts. On January 12th the commissioners issued a circular to the boards of selectmen, as follows: "You are hereby notified that a cattle quarantine against the State of Massachusetts is this day ordered. You are directed to seize and hold in quarantine all cattle not intended for immediate slaughter coming into this State from Massachusetts after this date, and to notify this Board at once of such action. Cattle from Massachusetts intended for immediate slaughter will be subject to quarantine regulations if any contagious or infectious disease is found among them; otherwise they will be allowed to proceed to their destination. All other cattle brought into the State without a permit from this Board, must be held by you, as above directed, until this order is cancelled."

NEW YORK.

MORTALITY FOR THE WEEK.—The number of deaths reported in the city for the week ending January 2d, was 969, an increase of 80 over the previous week, and showing an annual death-rate of 26.63 per thousand of the estimated population. Of this number 86 were attributed to influenza and complications.

THE DOCTOR'S WEEEKLY.—A newspaper devoted to the interest of the medical profession, was started with the new year by Dr. Ferdinand King, recently editor of *The International Journal of Surgery*.

TUBERCULOCIDIN.—The first instalment of tuberculocidin, or Kleb's modified tuberculin, has been received at the St. Mark's Hospital.

BEQUESTS TO PUBLIC INSTITUTIONS.—By the will of Mrs. Mary Stuart, widow of the late Robert L. Stuart, several million dollars is given to religious and charitable institutions and societies. Among these are the New York Cancer Hospital, which gets \$25,000, the Presbyterian Hospital, the Northwestern Dispensary, the Home for Incurables, the New York Eye and Ear Hospital, the Woman's Hospital, the Manhattan Eye and Ear Hospital, and the Society for the Relief of the Ruptured and Crippled.

Miscellany.

VITAL STATISTICS OF NEW YORK CITY, 1891.

DURING the year just closed the total number of deaths reported to the New York Bureau of Vital Statistics was 43,634, showing an annual death-rate of 25.96 per thousand of the estimated population. In the year 1890 the number of deaths reported was 40,230, and the annual death-rate 24.66. The total number of births reported was 46,894, against 30,250 in 1890; this large increase being due to the fact that since last spring the Health Department has made special efforts to secure reports from physicians and midwives who were negligent in reporting births.

The comparative number of deaths from certain diseases in the two years is shown in the following table:

	1891.	1890.
Influenza	838	314
Pneumonia	5,817	5,611
Phthisis	5,160	5,023
Bronchitis	1,834	2,037
Bright's disease	2,503	2,420
Disease of the heart	2,287	1,982
Diarrheal diseases	3,585	3,349
Small-pox	2	2
Measles	664	726
Scarlet fever	1,221	466
Diphtheria	1,363	1,351
Whooping-cough	353	489
Cerebro-spinal meningitis	189	137
Typhoid fever	384	332

In the Bureau of Contagious Diseases there were reported 25,189 cases, which included nine of typhus fever, 1,329 of typhoid fever, 7,218 of scarlet fever, 11,863 of measles, 4,749 of diphtheria, and 21 of small-pox. The vaccinating corps made 109,213 vaccinations; of which 83,970 were revaccinations.

THERAPEUTIC NOTES.

ANTIDOTE FOR HYDROCYANIC ACID.¹—Professor Kober has proved experimentally that hydrogen peroxide is a valuable antidote for hydrocyanic acid poisoning. It is to be given internally as well as subcutaneously until the odor of the acid can no longer be recognized in the exhalations and the symptoms subside.

THE TOXICITY OF THE URINE.²—Prompted by the view that various toxic products are eliminated in the urine in acute infectious diseases, Semmola, before the Académie de Médecine, expressed the thought that, by

¹ Pharm. Central, 570.

² American Journal of Medical Science, December.

the injection of such urine in rabbits and guinea-pigs, the symptoms of the original disease would be reproduced. Such a procedure would constitute a valuable diagnostic aid. Thus, for instance, in a case of influenza-pneumonia, complicated by tetanic and eclamptic attacks, the injection of the urine should reproduce the symptoms in animals, and meningitis could be excluded.

RESORCIN IN LARYNGEAL PHTHISIS.³—Dr. Ty-mowsky considers resorcin the most convenient of all local applications, because it gives no pain, and need only be applied once a day. The solution must be of the strength of one hundred per cent. in cases of unhealthy-looking ulcers, which are undoubtedly of tuberculous character. At the same time inhalations of from two to five per cent. solution of resorcin may be substituted for those of cocaine.

Correspondence.

MEDICAL NOTES FROM JAPAN.

TOKYO, JAPAN, December 5, 1891.

MR. EDITOR:—Through the kindness of Professor Boditz, M.D., I visited the Imperial University Hospital. It is arranged in pavilions, with accommodations for two hundred patients of both sexes. A large number, are "tuberculous"—pulmonary, or otherwise.

Leprosy is not considered eminently contagious; and is not excluded from the general wards. I saw one case, of long standing, where the appearance was typical, but would scarcely attract attention on the street. It is observed here, that of late, tuberculous affections are less numerous while leprosy has increased. The apparent relation of these two diseases may be explained by their bacilli being similar, if not identical.⁴ A class of students were receiving clinical instruction at the hour of my visit, 9 A. M.

Dr. Ishiguro (surgeon-general of the army) very kindly gave me a card to Dr. Hori, surgeon in charge of the large hospital under direct control of the War Office. Several long, one-story buildings, each separate from the others, afford room for the reception of four hundred persons.

By courtesy of Dr. Adachi (senior surgeon of the army) and Dr. Nalecsihana (staff surgeon), I was enabled to see the Army Medical College (Gun-iakkō) and Museum, a new brick building. The college has, at present, forty officers, as students. Everything is well arranged, with a view to practical results. Appliances for microscopic and bacteriological work were in place. The museum contains a good collection, illustrative of various means for care of the sick in field and hospital—some from different foreign sources. Among the pathological specimens is the extensive exhibit of lesions of bones, from the last civil war. In the Imperial University, German is the foreign language used for medical instruction; law and chemistry are taught by means of French and English.

I am indebted to Dr. W. N. Whitney (official interpreter to the United States legation) for an opportunity to observe the work at the Akasaka Hospital (Ophthalmic) under his professional direction. The beginning of this charitable and educational enterprise was made in 1883 by Dr. Whitney and Dr. Yoshida (now of the Japanese navy). The building in use was opened for patients in 1886, Dr. Mitamura being superintendent. This institution is supported by voluntary donations, foreign and Japanese. During the past five years these have amounted to about five thousand dollars. The medical work has been conducted by three attending surgeons, one house-surgeon, one apothecary, one student and two nurses. From June 30, 1890 to

³ In the Hawaiian Islands lepers are promptly removed from the general community to an isolated locality.

⁴ Lancet, November 21st.

June 30, 1891, the number of in-patients treated was 210; number of days under treatment, 2,732; number of dispensary consultations, 4,952; number of days medicine given, 12,306. Most of those attending are among the poorer classes, yet over one-fourth the running expenses has been paid by the patients. Some come more than sixty miles for medical care. The present structure has space for forty beds. Further extension is needed to provide for holding the dispensary service separate from the wards.

There is much blindness, due largely to keratitis consequent upon "disease" and uncleanliness during infantile life and later years. Many cases are doubtless the result of exposure to sun, wind and dust which children undergo. Being fastened securely to the shoulders of a nurse, herself quite young, the little one often cries and kicks in vain, frequently falling asleep with the face toward the hot sun.

It is said here, that rice-eating nations are less affected with cataract than other peoples; also, that rickets and consequent deformities are common among the Chinese and Japanese.

Very truly yours.

F. B. STEPHENSON, Surgeon, U. S. N.

uncharitableness are wiped out, — and the world is moving toward that end, — we shall see for all men of whatever avocation, not slander and calumny, but honor and justice for good work done."

Very truly yours,
J. WARREN ACHORN, M.D.

ADDRESSES WANTED.

MASSACHUSETTS MEDICAL SOCIETY, TREASURER'S OFFICE,
NO. 430 WEST CHESTER PARK.

BOSTON, January 7, 1892.

MR. EDITOR: — If any of your readers can and will inform me of the present whereabouts of

Thomas Goff Simons, M.D. (Bellevue), 1876, who became a Fellow, September 20, 1887, at Springfield, then thirty-three years of age, or of

Theodore Everett, M.D. (Harv.), who became a Fellow, October 17, 1888, at Haverhill, then twenty-six years of age, I will be obliged.

Dr. Simons was a student at Montreal University, but not a graduate, was three years at Bellevue, and studied also with Dr. W. V. Wallace, of Providence, R. I. He practiced at Springfield, his last known address.

Dr. Everett was educated at Phillips Academy, Exeter, studied medicine with Dr. Allan Mott-Ring, of Arlington Heights, and at the New York University and Harvard Medical Schools. He practiced at Haverhill, and then at Cambridge, his last known address.

Yours very truly,
EDWARD JACOB FORSTER, Treasurer.

VINDICATION OF DR. STERLING POMEROY.

BOSTON, Boylston Street, January 7, 1891.

MR. EDITOR: — At a complimentary dinner given Dr. Sterling Pomeroy, January 6th, at the Hotel Thorndike, by his friends, which I had the pleasure of attending, I gave expression to a few thoughts for which I request publication in the JOURNAL.

Dr. Pomeroy, as you know, has just been exonerated in the Gleason divorce trial from any unprofessional conduct; and it is on account of his trying position that I have been led to express myself as I have here:

"When we are sick it is not the lawyer we are looking for; it is not the priest; but it is the best physician in the town we want; and we want him bad. And he comes, perhaps without his dinner, perhaps without his sleep; for he's everybody's servant, and his masters cannot wait. By means of his trained skill and strength of body and mind, he works a cure. And his patient praises, and pays him. And both are satisfied.

"Again he is summoned, and his professional skill and patience are taxed as never before. For weeks he works, and for poor pay, or goes unpaid. For it is a servant's business to come as he is bid. And again he is praised — proportionately, perhaps.

"There are times — and times — and times when he ought to be blessed; and there are times, I know, when it were better he were condemned.

"Now if it were disease alone — disease *per se* — that he were treating, he would succeed. We should all succeed, for I believe that every fever ill to which poor human flesh is prone will in time find its end in a specific cure. It is not the disease then, but it is that indefinable factor in human beings — spirituality *perverted* — to which the good name of men of our calling is often sacrificed.

"We have to treat bodies and minds. The bodies we can take care of; but the minds — expressing themselves in all sorts of jealousies, sentimentalities and hypochondriacal ways — no matter what precautions we take, we cannot at all times escape these. Neither can we escape the suspicions of those who give credence, or partial credence, to the first rumor — the world at large. It is only when the minds and morals of the people have been educated up to the level of the morality and mentality of the physician of to-day that we can escape the imputations cast upon us, and that we can do our greatest work.

"I would like to see my eighty-first grandfather back. Probably he lived in southwestern Asia, and spent his days among the trees. I wonder what his language was. A succession of growls? Ten generations ago he was a garrulous old Gaul, and had his den on the head-waters of the Rhine. When in the evolution of the race and the growth of spirituality, jealousy, envy, hatred and malice and all

Deaths reported 4,200; under five years of age, 1,348; principal infectious diseases (small-pox, measles, diphtheria and croup,

diarrhoeal diseases, whooping-cough, erysipelas and fevers) 559, acute lung diseases 873, consumption 386, diphtheria and croup 280, scarlet fever 89, typhoid fever 84, diarrhoeal diseases 41, whooping-cough 23, erysipelas 13, measles 12, cerebro-spinal meningitis 12, malarial fever 3.

From medical diseases New York 13, Chicago 12, Brooklyn 11, Philadelphia 3, Baltimore 2, Milwaukee, Worcester, Lowell, Lynn, Springfield, and Hyde Park 1 each. From whooping-cough Philadelphia 5, New York 4, Boston 3, Brooklyn and Milwaukee 2 each, Baltimore, Cleveland, Washington and Springfield 1 each. From erysipelas New York 6, Chicago 3, Philadelphia, Brooklyn, Boston, Baltimore, Cleveland and Washington 1 each. From measles Chicago and Brooklyn 4 each, New York and Milwaukee, 2 each. From cerebro-spinal meningitis Chicago 6, Washington 2, New York, Philadelphia, Brooklyn and New Bedford 1 each. From malarial fever New York 2, Cleveland 1.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,405,108, for the week ending December 19th, the death-rate was 19.1, Deaths 1,340; acute diseases of the respiratory organs (London) 337, whooping-cough 122, measles 102, diphtheria 17, fever 46, diarrhoea 39.

The death-rates ranged from 10.8 in Nottingham to 32.8 in Newcastle-on-Tyne, Birmingham 16.5, Bradford 16.6, Hull 17.1, Leeds 20.1, Leicester 17.6, Liverpool 24.1, London 17.9, Manchester 21.6, Sheffield 21.5, Sunderland 30.6.

In Edinburgh 26.9, Glasgow 24.6, Dublin 33.9.

METEOROLOGICAL RECORD.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 2, 1892, TO JANUARY 9, 1892.

Leave of absence for one month on surgeon's certificate of disability is granted FIRST-LIEUT JAMES D. GLENNAN, assistant surgeon, U. S. A., with permission to go beyond the limits of the department.

Leave of absence on surgeon's certificate of disability granted CAPTAIN JEFFERSON R. KEAN, assistant surgeon, U. S. A., is extended three months on account of sickness.

MAJOR JULIUS H. PATAKI, surgeon, and CAPTAIN HENRY G. BURTON, assistant surgeon, having been found incapacitated for active service by the Army Retiring Boards, will proceed to their homes and on arrival there report by letter to the Adjutant General of the Army.

Leave of absence for six months with permission to go beyond the sea, to take effect on or about January 27, 1892, is granted MAJOR JAMES F. KIMBALL, surgeon, U. S. A.

MAJOR ALFRED A. WOODHULL, surgeon, U. S. A., having returned to the United States, is relieved from further duty and station at Fort Sherman, Idaho, and assigned to temporary duty in New York City.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 9, 1892.

M. R. PIOTT, assistant surgeon, from hospital, Mare Island, Col., and to the U. S. S. "Baltimore."

E. R. STILT, assistant surgeon, from U. S. S. "Baltimore" ordered home and two months' leave of absence granted.

M. S. GUEST, assistant surgeon, to the Navy Yard, Norfolk, Va.

C. H. WHITE, medical inspector, from the U. S. S. "Charleston," proceed home and granted two months' leave.

J. B. PARKER, surgeon, ordered to the U. S. S. "Charleston."

SOCIETY NOTICE.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT.—The Section for Clinical Medicine, Pathology and Hygiene, will meet at 19 Boylston Place, on Wednesday, January 20th, at 7.45 o'clock.

In Memoriam.—David Humphries Storer, George Hinckley Lyman.

Dr. Storer.—Dr. S. L. Abbott, Dr. G. J. Townsend, of Natick, Dr. O. W. Holmes, Dr. A. D. Sinclair, Dr. G. G. Tarbell, Dr. A. T. Cabot, and Dr. E. G. Cutler are expected to make a few remarks.

Dr. Lyman.—Dr. C. Ellery Stedman, of Dorchester, Dr. H. W. Williams, Dr. J. G. Blake, Dr. A. L. Mason, and Dr. George B. Shattuck will speak.

ALBERT N. BLODGETT, M.D., Sec'y, 390 Boylston St.

E. G. CUTLER, M.D., Chairman.

MASSACHUSETTS SCHOOL FOR THE FEEBLE-MINDED.

The Massachusetts School for the Feeble-Minded has been moved to Waltham, near the Clematis Brook Stations of the Fitchburg and the Massachusetts Central Division of the Boston and Lowell Railroads. The railroad fare is fifteen cents each way. The distance from Boston is eight miles. The post-office, telegraph and express address is Waverley, Mass. Packagings for the children should be addressed to the School at Waverley. Always put the child's name on the inside of the package. CLEMATIS BROOK is the nearest railroad station. Friends of the children may visit them any afternoon, holidays and Sundays excepted. All communications should be addressed to

WALTER E. FERNALD, M.D., Sup't, Waverley, Mass.

RECENT DEATHS.

EDWARD S. BERRY, M.D., of Concord, N. H., died recently, aged forty-seven.

JOSEPH HILTON, M.D., of New York, died January 7th, aged seventy-seven.

COLIN MACKENZIE, M.D., of New York, died January 6th, aged fifty-three. He served with distinction in the medical corps of the army during the war.

HORATIO S. HENDER, M.D., died in Lowell, N. Y., January 10th, aged sixty-two. He served in the war as surgeon of the one hundred and fifty-eighth New York regiment.

JOHN WOOD, F.R.S., F.R.C.S., Emeritus Professor of Surgery in Kings College, London, died December 29th, aged sixty-six.

W. H. LONG, M.D., surgeon in the Marine Hospital Service, died at Cincinnati, January 2d, aged forty-nine. He was appointed assistant surgeon in 1875, and surgeon in 1878. He has been in Cincinnati since 1888.

ERNEST WILHELM BRUCKE, Professor of Physiology and Microscopic Anatomy, in Vienna, died January 7th, aged seventy-two. He had been professor in Vienna since 1849. He was a member of the Academy of Sciences, and is the author of several works on different physiological subjects.

BOOKS AND PAMPHLETS RECEIVED.

The Technique of Cerebral Surgery. By G. Wiley Broome, M.D., St. Louis. Reprint. 1891.

Concealed Pregnancy: Its Relations to Abdominal Surgery. By Albert Vander Veer, M.D., Albany, N. Y. Reprint. 1889.

The Aseptic Closure of Long Standing Sinuses having their Origin in Tubercular Joints. By H. Augustus Wilson, M.D., Philadelphia.

Retro-peritoneal Tumors: Their Anatomical Relations, Pathology, Diagnosis and Treatment. With a Report of Cases. By Albert Vander Veer, M.D., Albany, N. Y. Reprint. 1892.

THE SANITARY CONDITION OF BOSTON: A STATISTICAL PAPER.¹

BY J. H. MCCOLLON, M.D.

THE remark is frequently made that the death-rate of Boston is exceptionally high; much higher than that of some of the principal cities in this country and in Europe. To show that this statement, while correct so far as the rate from certain diseases is concerned, is incorrect when the general death-rate is taken into consideration, is the object of this paper. The general death-rate of a city is not always a perfectly reliable indication of its sanitary condition because, as the population is either increasing or diminishing, the ratio of deaths may be very much over-estimated or under-estimated. The most satisfactory plan for obtaining correct information on this point is to find the percentage of deaths from any one disease or from any class of diseases to the total mortality. For the purpose of comparison the following five cities have been selected: New York, Philadelphia, Glasgow, Edinburgh and Berlin.

The death-rate in Boston, per one thousand was 22.70, for 1890. The rate for the preceding year was 24.42, and the average rate for the past ten years has been 23.47. The highest death-rate reached in this city in the past twenty-five years was in 1872, during the small-pox epidemic when the proportion was 31.80; in 1873 the rate was nearly as high being 30.27. In New York City the rate for 1890 was 24.58; in 1872, the year of the small-pox epidemic, it was 33.70. For the last ten years the ratio has ranged from 30.99 to 24.58, with an average of 26.56. In Philadelphia the rate for 1890 was 20.76. In 1872 it was 26.19. For the last ten years, ending with 1890, the average has been 21.43. Glasgow has had for the same period, an average rate of 25.21. The rate for 1890 is 25.20. It is worthy of note that in Glasgow the average rate for ten years, and the rate for 1890, are practically the same. Edinburgh has an average for the decade commencing in 1881 of 19.40. The rate for 1890 is 20.00. In Berlin the rate for 1890 is 21.51. The average rate for the last ten years, 1881 to 1890 inclusive, is 24.37. In 1872, the year of the small-pox epidemic, the rate was 31.00; in 1875, when there was no general epidemic, the rate was 32.92; in 1883, the rate was 28.86. Boston during these three years had respectively a rate of 31.80; 24.95, and 22.76.

So far as the death-rate from all causes for the decade ending with 1890 is concerned, the six cities just mentioned should be placed in the following order: Edinburgh, with an average rate of 19.17, stands at the head of the list, having the lowest ratio; then comes Philadelphia, with a rate of 21.43; then Boston, 24.47; then Berlin, 24.52; next Glasgow, 25.21, and last New York, 26.50. If the rate for 1890 alone is taken, the order would be; Edinburgh, 20.00; Philadelphia, 20.76; Berlin, 21.51; Boston, 22.70; New York, 24.58; and Glasgow, 25.20. The epidemic of influenza, which had a very considerable effect on the death-rate from pulmonary diseases is one cause of the comparatively high death-rate of Boston and New York in 1890. The effect of this

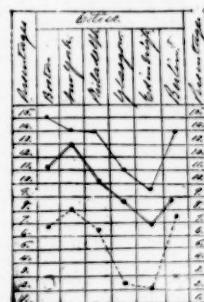

epidemic was felt in Europe in 1889. The estimated death-rate in Boston for 1891 is 21.28.

The average density of population does not have such a direct influence on the general death-rate of a city as has been supposed, although its effect on the number of deaths from special diseases is often very marked. The reason of this is evident; certain districts in a city are crowded, while others are sparsely settled. In no city is this condition more apparent than in Boston; for instance, Ward 16 with a population of 184 to the acre as compared with Ward 23 with only three to the acre. In support of this statement it is worthy of notice that Edinburgh with a death-rate of 20 to the thousand, has an average population of 101 to the acre, while Glasgow, with a rate of 25.20, has 87; that Berlin, with a rate of 21.51, has 110, while Philadelphia, with a rate of 20.76, has only 13 to the acre. If Boston, with a rate of 22.70 and a population of 20 to the acre, is compared with New York with a rate of 24.58 and a population of 111 to the acre, it will be seen that, although the rate is higher and the population larger in the latter city than in the former, the increase in the death-rate bears no direct relation to the increase in the density of the population.

CHART A.

PERCENTAGE OF DEATHS FROM CONSUMPTION, DIARRHEAL DISEASES AND PNEUMONIA TO THE TOTAL MORTALITY IN BOSTON, NEW YORK, PHILADELPHIA, GLASGOW, EDINBURGH AND BERLIN, 1890.

Consumption = — Pneumonia = — Diarrheal disease =

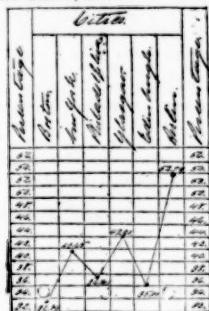

The most important factors in causing the comparatively high death-rate of Boston are consumption, diarrheal diseases and pneumonia. The percentage of deaths from these three causes to the total mortality during 1890, in the six cities just mentioned, is as follows: Boston, 31.93, the highest; Berlin, 29.19; New York, 26.92; Philadelphia, 23.88; Glasgow, 20.72; and Edinburgh, 17.14. If these three diseases are taken separately, it is evident from a study of Chart A, which shows the percentage of deaths from these three causes to the total mortality, that, by following the full line, which indicates the percentage of deaths from consumption, Boston has the highest rate, 14.68; New York comes next, 13.69; Philadelphia, 13.46; Berlin, 13.23; Glasgow, 10.42; and Edinburgh, 9.00. By following the double line, which indicates the percentage of deaths from pneumonia to the total mortality, it will be seen that the order is somewhat changed, New York having the highest rate, 12.44; then Boston, 10.72; Philadelphia, 9.81; Berlin, 8.34;

¹ Read before the Boston Society for Medical Improvement, November 23, 1891.

Glasgow, 8.25; and Edinburgh having the lowest, 6.30. It is interesting to note the course of the broken line, which shows the percentage of deaths from diarrhoeal diseases. New York has the highest rate, 7.84; then Berlin, Boston and Philadelphia with percentages of 6.99, 6.53, and 6.04. Glasgow and Edinburgh have nearly the same percentage; 2.05 in the former and 1.94 in the latter city.

CHART B.

PERCENTAGE OF DEATHS UNDER FIVE YEARS TO THE TOTAL MORTALITY IN BOSTON, NEW YORK, PHILADELPHIA, GLASGOW, EDINBURGH AND BERLIN, 1890.

The percentage of deaths of children under five years of age to the total mortality, is always an important factor in causing a high death-rate of a city. Sudden changes of temperature, crowding in tenement-houses, improper food, want of cleanliness, and a general neglect of sanitary measures are the chief agents in increasing this mortality. The subject of infant-feeding is such a vast one that it is entirely beyond the scope of this paper; but, as bearing on this matter, the statement in the *Statistisches Jahrbuch der Stadt Berlin*, for 1888, that the ratio of deaths in the first year of life, to the thousand, was 44.11 in children fed on animal milk, while it was only 7.90 in nursing children, is of interest. The effect of a high temperature on the mortality of children fed on animal milk as compared with nursing infants, is very marked. During the summer of 1888 in Berlin, the death-rate per thousand of the former was 28.43, for the other nine months of the year it was 15.68; the rates of the latter for the corresponding seasons were 4.06 and 3.84. Chart B indicates the percentage of deaths of children under five years of age to the total mortality for 1890, in the cities taken for comparison. It will be seen at a glance that Boston has the lowest rate, 32.89; that Edinburgh comes next, 35.00; then Philadelphia, 36.41; New York, 40.65; Glasgow, 43.20; and Berlin, 52.79. The density of population seems to have some slight influence on these percentages; for with the exception of Philadelphia, which should have a lower rate, and Edinburgh, which should have a higher, an increase in the density coincides, to a certain extent, with an increase in the percentage. This rate has gradually diminished in Boston since 1875, when it was 43.84. The average for the last five years is 34.86. The percentage for the first nine months of the present year, 1891, is 35.77.

The percentage of deaths from zymotic diseases to the total mortality shows a very decided decrease in

this city, having fallen in the past ten years from 26.87 to 16.47, a diminution of 10.40. The percentage for 1890 is 16.47, and the rate for the first nine months of the present year, 1891, is 16.10.

TABLE C.

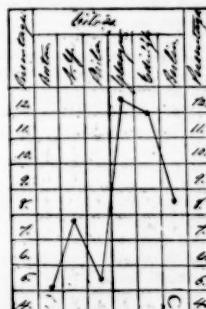

PERCENTAGE OF DEATHS FROM TEN PRINCIPAL CAUSES TO THE TOTAL MORTALITY IN BOSTON, NEW YORK, PHILADELPHIA, GLASGOW, EDINBURGH AND BERLIN, 1890.

Causes.	Boston.	N. Y.	Phila.	Glas.	Edin.	Berlin.
Bronchitis	4.50	4.95	2.55	11.86	16.65	.25
Consumption	14.68	13.69	15.46	10.42	9.00	13.23
Croup	.60	1.30	2.02	.53	.65	.28
Diarrhoeal diseases	6.53	8.34	6.64	2.05	1.94	6.39
Diphtheria	3.91	3.15	2.57	1.05	1.59	4.47
Measles	.19	1.82	.51	4.76	4.38	.99
Pneumonia	10.72	12.44	9.81	8.25	6.30	9.34
Scarlet fever	.41	1.02	.92	.96	.90	.89
Typhoid fever	1.52	.88	3.24	.88	.89	.43
Whooping-cough	.38	1.21	.99	5.22	4.54	1.76
Total	43.47	48.80	42.11	45.98	40.24	37.63

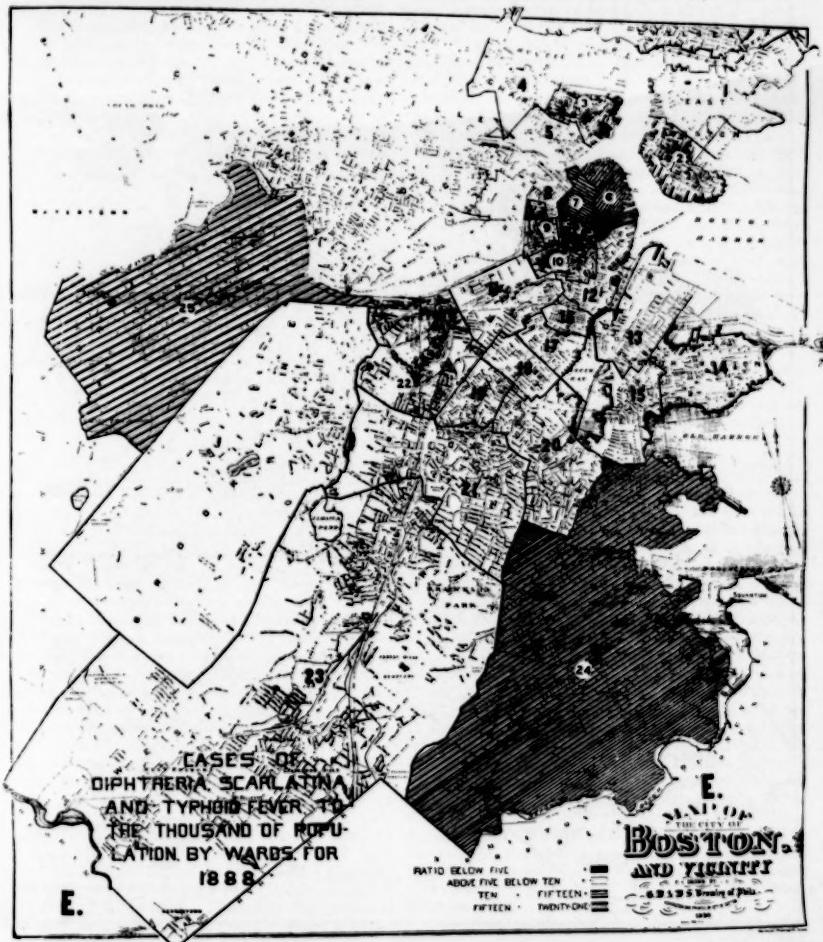

As the same nomenclature is not in use in different cities, a comparison of the relative mortality from zymotic diseases, taken together, cannot be made. Table C, however, gives the percentage of deaths from ten principal causes to the total mortality in six cities. It is evident from it that, during 1890, bronchitis was a very prominent factor in increasing the death-rate of

CHART D.

PERCENTAGE OF DEATHS FROM DIPHTHERIA, MEASLES, PERTUSIS AND SCARLATINA TO THE TOTAL MORTALITY IN BOSTON, NEW YORK, PHILADELPHIA, GLASGOW, EDINBURGH AND BERLIN, 1890.

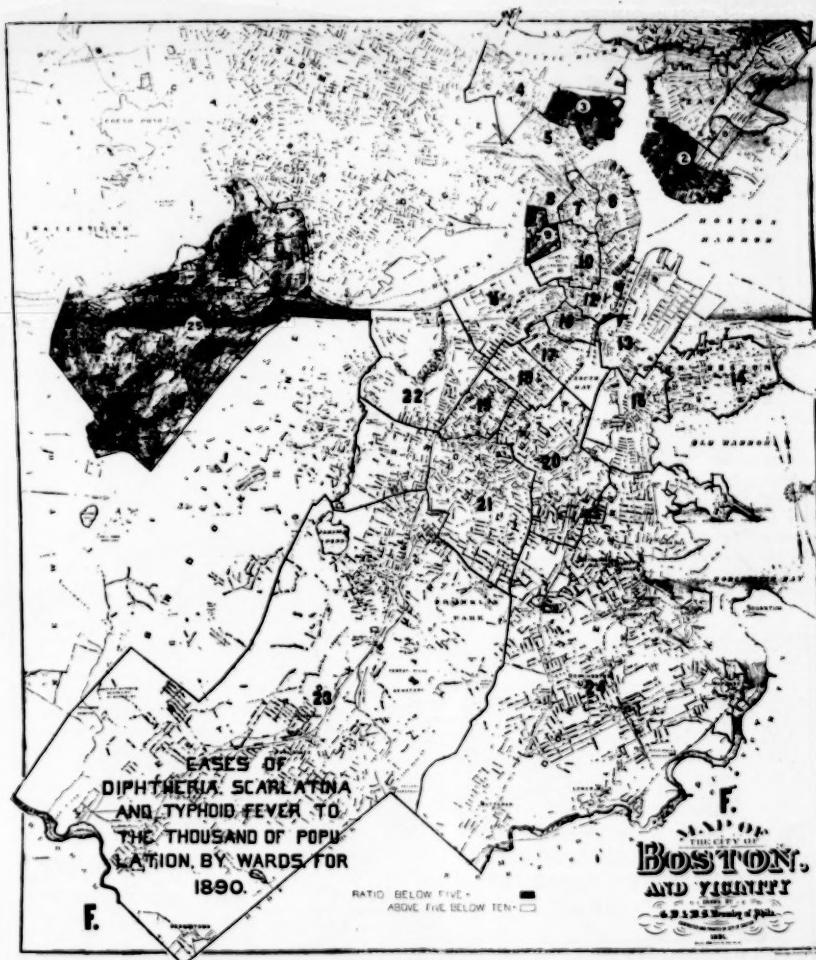

Glasgow and Edinburgh, while it had a comparatively slight effect on the rate of Boston and New York, and still less on that of Philadelphia and Berlin; that, except in New York and Philadelphia, croup does not have any great influence on the death-rate; that typhoid fever is twice as prevalent in Philadelphia as in Boston, more than three times as prevalent in New York, Glasgow and Edinburgh, and more than seven times as prevalent as in Berlin. It is an interesting fact that when croup and diphtheria are taken together there is a difference, in the relative frequency of these diseases, of only a quarter of one per cent.

between Boston, New York, Philadelphia and Berlin. The percentage of deaths from consumption, diarrhoeal diseases and pneumonia has already been shown in Chart A. If these ten principal causes are taken together the percentage to the total mortality is, in New York, 48.80; in Glasgow, 45.98; in Boston, 43.47; in Philadelphia, 42.11; in Edinburgh, 40.24; and in Berlin, 37.63. If the excess of the percentage of deaths from consumption and pneumonia in Boston is eliminated, it will be found that Boston has a lower rate than Philadelphia and Edinburgh, and a slightly higher rate than Berlin.

Chart D indicates the percentage of deaths from

pertussis, diphtheria, scarlet fever and measles to the total mortality in the cities before mentioned. It can be seen at a glance that Boston has the lowest percentage, 4.92; then Philadelphia, 4.99; New York, 7.20; Berlin, 8.11; Edinburgh, 11.41; and Glasgow, the highest, 11.99. The percentage of Boston is due principally to diphtheria; that of New York to diphtheria, measles and scarlet fever; that of Philadelphia to diphtheria; that of Glasgow and Edinburgh to measles and whooping-cough; and that of Berlin to diphtheria and whooping-cough. It is an interesting fact as bearing on the fatality from certain diseases in different countries, that the percentage of deaths

from measles and whooping-cough in Glasgow and Edinburgh is three times as great as that of the other cities. In Boston, since the year 1887, the percentage of deaths from diphtheria and scarlet fever to the total mortality, has diminished from 5.07 to 4.35. The percentage for the first nine months of this year, 1891, is 1.94. During the last five years the percentage of deaths from measles and whooping-cough has fallen from 2.62 to .57. These diseases have not been a very important factor in the death-rate of Boston for the past ten years; the highest percentage from measles having been 1.56; and that from whooping-cough 1.88. Of the preventable diseases, diphtheria, scarlet fever and typhoid fever are the most prominent

agents in increasing the death-rate of Boston. Map E represents, in a general way, the ratio of cases of diphtheria, scarlet fever and typhoid fever to the thousand of population in the different wards of the city for 1888.

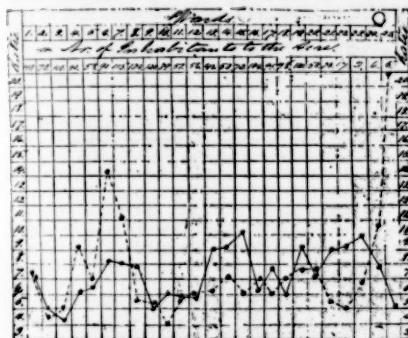

Map F shows the ratio of cases of these diseases to the thousand, by wards, in 1890. On these maps the wards, in which the ratio is below five to the thousand, have a dark shade; when the rate is above five and below ten, the wards are white; when the ratio is above ten and below fifteen the wards in which this ratio occurs are indicated by wide black lines alternating with narrow black ones; wide black lines alternating with two hair lines indicate a ratio above

fifteen. If these maps are compared it will be seen that on the one for 1888 five wards have a rate below five to the thousand, sixteen wards have a rate above five and below ten, three have a rate above ten and below fifteen, and one has a rate above fifteen; that on the map for 1890, four wards have a rate below five, and in the remaining twenty-one the rate does not exceed ten.

CHART G.

RATIO OF CASES OF DIPHTHERIA, SCARLATINA AND TYPHOID FEVER TO THE THOUSAND OF POPULATION, BY WARDS, IN BOSTON FOR 1888 AND 1890, WITH THE NUMBER OF INHABITANTS TO THE ACRE IN 1890.

1888 = 1890 =

A somewhat more accurate idea of the relative frequency of diphtheria, scarlatina and typhoid fever in the different wards for 1888 and 1890 may be gained from Chart G, which shows the ratio of these diseases to the thousand with the number of inhabitants to the acre in each ward in 1890. The basis for the calculation of the ratio of 1888 was obtained by multiplying the number of assessed polls by 3.45; that for 1890 was the last United States census. The acreage of each ward was furnished by the City Surveyor, and is approximately correct. The broken line indicates the ratio for 1888; the full line that for 1890. The rate for 1888 in Ward 1, with an average population of 49 to the acre, was 6.91; that for 1890 was 6.46. In Ward 2, with a population of 70 to the acre, the rate for 1888 was 3.90; that for 1890 was 4.68. Ward 3 has a population of 40 to the acre. The ratio in 1888 was 4.69; in 1890, 3.74. The population of Ward 4 is 42 to the acre. The ratios for 1888 and 1890 are 8.89 and 5.68, respectively. Ward 5, with a population of 58 to the acre had, in 1888, a rate of 6.42; in 1890 the rate was 5.96. It is of interest to notice that, in the five wards just mentioned, comprising East Boston and Charlestown, the ratio is lower in the poorer localities than it is in the better. This condition is due to the fact that a greater proportion of the patients are sent to the hospital from the former localities than from the latter, thus removing many sources of contagion.

Ward 6, with a population of 90 to the acre, the rate in 1888 was 13.78; in 1890, 7.86, a diminution of 5.92. In Ward 7, which has a population of 115 to the acre, the rate in 1888 was 10.77; in 1890, 7.68, a marked diminution. In Ward 8, the average population is 184 to the acre. The rate in this ward for

1888 was 5.20; that for 1890 was 7.44, an increase of 2.24. The population of Ward 9 is 120 to the acre. The rate for 1888 was 4.82; that for 1890 was 4.66. Ward 10, which has a population of only 39 to the acre, had a ratio of 3.76 in 1888; the rate in 1890 was 5.48, a slight increase. The population of Ward 11 is 51 to the acre. The rate for 1888 was 5.34; that for 1890 was 5.44. The population of Ward 12 is 56 to the acre. The rate in 1888 was 5.52; in 1890, it was 5.32. Ward 16 is the most thickly settled district in the city, having a population of 184 to the acre. The rate in this ward, for 1888, was 6.46; for 1890, 5.70. The number of inhabitants to the acre in Ward 17 is 95. The ratio for 1888 was 6.54; that for 1890 was 7.16, a slight increase. Ward 18 has a population of 78 to the acre. The ratio for 1888 was 6.64; the rate for 1890, 5.55, slight diminution.

In the city proper, embracing the ten wards just mentioned, the most marked diminution in the number of cases occurred in Wards 6 and 7. In Wards 18, 14 and 15, comprising South Boston, with a population, to the acre, of 42, 53 and 72, respectively, there was a considerable increase in the frequency of these diseases in 1890 as compared with 1888. The rate for the former year was 8.53, 8.83, 9.80, respectively; that of the latter 5.93, 6.70 and 5.80. In Wards 19, 20, 21 and 22 with a population, to the acre, of 100, 50, 30 and 17, respectively, the ratio for 1888 was 7.16, 7.11, 5.06 and 4.51; that for 1890 was 8.86, 6.90, 8.41 and 8.74, respectively. In the four wards just mentioned, which practically embrace the district known as Roxbury, there was an increase in the frequency of these diseases in 1890 as compared with 1888. In Ward 23, or West Roxbury, with a population of three to the acre, the rate in 1888 was 6.21; in 1890, 9.24. Ward 24, or Dorchester, has a population of six to the acre. The rate in this district was 10.01 for 1888; that for 1890 was 7.32, a marked diminution. Brighton, Ward 25, with a population of five to the acre, had, in 1888, the remarkable rate of 20.31; in 1890, the rate was 4.82, a decrease of 15.49. In the whole city the ratios for diphtheria, scarlatina and typhoid fever taken separately were, in 1888, 3.32, 1.66, 2.17; in 1890, 2.29, 2.06 and 1.89, respectively. The ratio of these diseases to the thousand, taken together, in the whole city, was, in 1888, 7.15; in 1890, 6.24. It may be of interest to note the ratio of these diseases in the different sections of the city for 1890: Brighton has the lowest rate, 4.82; Charlestown, 5.11; East Boston, 5.63; Boston proper, 6.26; Dorchester, 7.32; Roxbury, 8.19; South Boston, 8.99; and West Roxbury, 9.24.

Chart H shows the ratio of cases of typhoid fever to the thousand of population by wards in 1890. The wards in which the ratio was above one and one-half to the thousand were 1, 2, 4, 5, 6, 9, 10, 11, 12, 13, 14, 16, 17, 19, 20, 22 and 23; those in which the ratio was below one and one-half were 3, 7, 8, 15, 18, 21, 24 and 25. It is worthy of notice that the rate in Ward 6 is 2.81, while that of Ward 7 is only 1.21; that the rate of Ward 16 is comparatively low, while that of 17, the adjoining ward, is comparatively high. The rate of 2.64 in Ward 23 with a population of only three to the acre may be explained by the existence, in this locality, of a number of wells. An infected well is one of the most potent factors in the causation of this disease; it is, in fact, a culture tube on a large scale.

It is an interesting fact, bearing on the subject of a public water-supply as compared with wells, that in Charlestown, in which the Mystic water is used, the rate is not particularly high, in the poorer localities, where the residents remain at home during the whole year, while in those districts where the inhabitants leave the city during the summer months the rate is considerably increased. This statement is also true, with certain limitations, of the other parts of the city.

CHART H.

RATIO OF CASES OF TYPHOID FEVER TO THE THOUSAND OF POPULATION, BY WARDS, IN BOSTON FOR 1890, WITH THE NUMBER OF INHABITANTS TO THE ACRE.

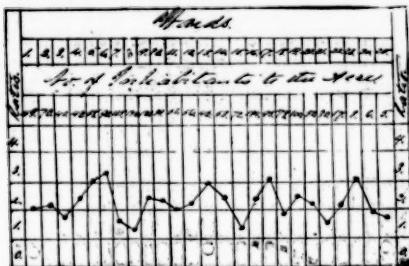

Table I gives the ratio of cases of typhoid fever to the thousand of population in the different wards of the city for 1890, and is explanatory of Chart H.

TABLE I.

RATIO OF CASES OF TYPHOID FEVER TO THE THOUSAND OF POPULATION, BY WARDS.

Ward 1, East Boston	1.68	Ward 14, South Boston	2.12
" 2, "	1.79	" 15, "94
" 3, Charlestown	1.37	" 16, Boston	1.93
" 4, "	1.94	" 17, "	2.68
" 5, "	2.41	" 18, "	1.37
" 6, Boston	2.81	" 19, Roxbury	2.08
" 7, "	1.21	" 20, "	1.84
" 8, "92	" 21, "	1.04
" 9, "	2.05	" 22, "	1.69
" 10, "	1.95	" 23, West Roxbury	2.64
" 11, "	1.47	" 24, Dorchester	1.41
" 12, "	1.82	" 25, Brighton	1.32

The percentage of deaths from diphtheria, scarlatina and typhoid fever to the total mortality for the nine months ending with September 30th of the present year, 1891, is 3.15; that for the corresponding nine months of 1890, was 5.89, a diminution of 2.74. The number of reported cases of these diseases for the same period in 1891 is 1,942, as compared with 2,483 in 1890, a decrease of 541 in the number of cases.

It has been shown from this collection of statistics:

- (1) That the general death-rate of Boston is not exceptionally high.
- (2) That the excess of the death-rate in Boston, over the five cities taken for comparison, is due to consumption and pneumonia.
- (3) That the percentage of deaths of children under five years of age to the total mortality is lower in Boston than in any other of these five cities.
- (4) That the percentage of deaths from diphtheria, measles, pertussis and scarlet fever to the total mortality is also lower in Boston than in any of these cities.
- (5) That, in this city, during the past two years, there has been a marked diminution in the number of cases of diphtheria and scarlet fever.

THE TREATMENT OF CHRONIC SPRAINS OF THE FINGER-JOINTS.¹

BY ROBERT W. LOVETT, M.D., OF BOSTON.

I FEEL that I owe the Society an apology for presenting a paper upon so trivial a subject; but the affection in question is a common one, and one which is exceedingly intractable and troublesome, and I have not been able to find any satisfactory mention of its character or treatment in the text-books. It is not uncommon in surgical practice, and in the last two years a fairly large number of cases have come under my observation in private and in hospital practice. It seemed to me that it might be of practical interest to mention the peculiarities of the affection and to cite one or two individual cases, at the same time speaking of a plan of treatment which is not by any means new, I fancy, but which has proved successful in the largest proportion of the cases which have come under my observation.

The greater proportion of cases among those that I have seen have occurred in women, although men have by no means been exempt; and in both men and women neurasthenic symptoms have in many cases been associated with the local symptoms of synovitis. In the greater majority of cases the finger synovitis was due to some injury, such as a strain or hyperextension of the joint; but in several instances the patient could assign no cause for the synovitis, although it is likely that in these there was some overuse of the affected finger or some unconscious traumatism.

The joints most often affected have been the phalangeal articulations, and on examination they have been seen to be enlarged, and most often shiny. Sensitiveness is very marked, especially over the lateral ligaments, and local heat is a common symptom. Motion is very much restricted, or complete stiffness of the affected joint may be present, and attempted manipulation is very painful. Generally the sprained joint is held in a position of partial flexion, and any attempt to extend it is very distressing. In severe cases the whole finger may be swollen.

The pain and sensitiveness in general are more than would be expected from the local symptoms. The swelling may often be considerable, and fluctuation may be present, due to the synovial distension; but these are not necessarily the most painful cases. In other cases, with comparatively little enlargement of the joint, much sensitiveness may be present, and the pain may be severe enough to keep the patient awake at night. It is this disproportion of pain and local symptoms which makes this especial affection noteworthy, and distinguishes it in a measure from other sprains.

The association of neurasthenic symptoms with such finger sprains seems common enough to suggest that in many cases they are intimately associated pathologically. In these cases it is easy enough to account for the excess of pain, but this will not explain all instances where the sensitiveness seems excessive. The symptoms of which I speak are excessive nervousness, persistent basal headaches, tingling of the hands and feet, sensitive spots over the spine, and the like. I cannot state definitely in what proportion of cases these have occurred, but I am sure that some of them have been present in more than half of the cases that I have seen.

¹ Read before the Boston Society for Medical Improvement, November 23, 1891.

Most of the cases have been of some weeks' or some months' standing when they were seen. The affection seemed at first so trivial that it appeared to the patients not worth attending to, and it was only when it became apparent that it was not wearing off, but was getting progressively worse, that they applied for treatment.

The affection seems to show little or no tendency toward spontaneous improvement: in fact, the disposition seems to be to an increase of pain and sensitiveness over what followed the injury, and simple therapeutic measures seem of no avail.

One or two specimen cases may be of interest.

Miss A., forty years old, an artist, consulted the writer in the spring of 1889, with regard to a chronic sprain of the large phalangeal joint of the left middle finger. Six weeks previously she had wrenching the finger in opening a bureau drawer, and it had been lame for some time, and for three or four weeks it had been getting progressively worse. When seen by the writer the joint was swollen, hot and tender; no motion was allowed, and at night the finger was very painful. The patient was very nervous, and said that the previous spring she had had nervous prostration. For two weeks the finger was kept upon a splint and painted daily with iodine. This produced a very slight improvement, but not much. The splint was then removed for a few minutes at night and the finger soaked in hot water. This was followed by massage; and after a treatment extending over some six weeks, the usefulness of the finger was practically restored. The recovery has been permanent.

Jennie P., a mill hand, twenty-one years old, apparently well, although nervous, applied for treatment at the City Hospital in August, for a synovitis of the metacarpal-phalangeal joint of the thumb. It had been injured in November, eight months previously, and in May, six months after injury, it had become so bad that she gave up work and tried various remedies. At the time when she was seen the joint was swollen and very sensitive to pressure and manipulation. The thumb was immobilized for a month without any apparent effect and then the splint was gradually discontinued and massage begun, and in a month or six weeks more the use of the thumb was fully restored.

These cases will serve to recall the kind of case of which I speak, and to call attention to the extreme slowness of the recovery even under the most favorable conditions.

There is but little to be said with regard to the pathology of the affection, at first it appears to be a simple acute synovitis due to injury, but it soon assumes the type of a chronic synovitis and probably passes on into an arthritis in severe cases. That is, the bone becomes affected as well as the synovial membrane, causing thickening and distortion of the affected joint. It would seem that in cases where the stiffness had been of some months' standing, adhesions would have formed which would lead to obliteration of the joint, but even in such obstinate cases as the one last related, the restoration of perfect mobility seems possible in a large proportion of cases.

Rheumatism and rheumatoid arthritis undoubtedly have a part in keeping up certain cases of chronic finger sprains, but beyond this it is not possible to speak definitely of the etiology. Certain cases of spontaneous synovitis of the finger-joints clearly belong to this class.

The treatment which after much experimentation has seemed to be the best, is complete immobilization of the affected joint for a period of two to four weeks, followed by a gradual discontinuance of the splint and the use of massage and hot water.

In general the tin finger-splint has been used and the affected joint freely painted with iodine during the time of its immobility. In private practice it has been more comfortable to apply the copper-wire splint, which is done by winding the finger in sheet wadding and then winding a spiral of thin copper wire about it with one or two lengths running from the tip to the base of the finger. This gives complete and comfortable immobility, but requires constant adjustment and is liable to interfere with the circulation. After the finger has been immobilized for such time as seems best according to the severity of the case, the use of hot-water soaking is begun along with massage every second day. Gradually the splint is discontinued without much regard to the pain caused, and the patient encouraged to use the finger.

Two points have appeared to the writer to be established: one is that simple fixation, however prolonged, is not enough to cure the affection, and secondly, experience in the more severe cases has shown that the immediate use of massage is not tolerated. Consequently a period of immobilization must be insisted upon which at the time seems to be accomplishing very little, but which probably is an essential part of the treatment. And at the close of this period of fixation there is often but little improvement to be noted, and pain on movement seems perhaps as severe as in the first place. But this must be disregarded and massage begun.

Salicylate of soda three times a day, or oftener, in ten-grain doses, has formed part of the writer's treatment because in some cases there was evidently a rheumatic element, and because in the majority of cases it was found to control the pain and seemed to hasten the convalescence. The general condition often needs attention.

Once more may I call your attention to the fact that this affection does not tend towards spontaneous recovery, that its progress is in any event lamentably slow, and that it is often associated with neurasthenia.

A CASE OF BILIARY CALCULUS; CHOLECYSTOTOMY; DUODENAL FISTULA; RECOVERY.¹

BY J. F. A. ADAMS, M.D., PITTSFIELD, MASS.

MR. B., aged thirty-eight, married, manufacturer, residing at Bridgeport, Conn., consulted me November 22, 1890, and gave the following history:

For ten years past he has suffered from attacks of severe abdominal pain, at intervals varying from two or three weeks to two or three months. The first of these attacks was followed by local peritonitis, since which he has had four other attacks of peritonitis following the pain, which has always been in the region of the gall-bladder.

Two years ago, after an unusually severe attack, he had jaundice for the first time, accompanied with nausea and itching. In three or four weeks the skin resumed

¹ Read at the quarterly meeting of the Berkshire District Medical Society, July 29, 1891.

its normal color. Since then the attacks of pain have not usually been followed by jaundice.

In August, 1890, while in England on business, he had a severe attack of pain, followed by local peritonitis, but not by jaundice, except a slight yellow tinge of the conjunctiva. He returned home immediately after and suffered on the voyage from constant pain and tenderness. After reaching home he was confined to his bed for ten days with a temperature of 101° to 103° . Since that time the attacks of pain have increased in severity, and have occurred about once in two weeks, relieved only by hypodermic injections of morphia. Jaundice also appeared in September, and has since been persistent and very deep in color. Since jaundice appeared each attack has been accompanied with nausea, which had not previously occurred.

There has been constant tenderness over the gall-bladder since the attack in August, and the stools have been white or light clay-colored, as they have always been for a few days after an attack of pain. The urine has been coffee-colored. The patient has lost fifty pounds in weight during the last three months. He is naturally a robust, vigorous, cheerful man. He is now thin, yellow and feeble, with a haggard and dejected expression.

At this time I gave him some general advice, and advised an operation.

The patient came to see me again the last of December. He had had an attack of pain December 17th, since when the jaundice was diminished and he had felt generally better.

On December 30th I went with him to see Dr. William W. Seymour, of Troy, who had himself submitted to the operation of cholecystotomy in December, 1889, at the hands of Mr. Lawson Tait, and had reported his case in very attractive style in the *Medical Record* for December 6, 1890. Dr. Seymour gave us a detailed account of his former sufferings, of the operation, and of the completeness of the cure; showed us his cicatrix and phial containing his one hundred and fourteen calculi. We saw in him a big, active, athletic man, a monument to the success of cholecystotomy. Mr. B. was very favorably impressed, and made up his mind that he would submit to the same operation if the attacks continued. But as he then thought himself much better, he preferred to wait a little.

The next day, December 31st, while on his way to Bridgeport, he had one of his severest attacks, and during the next three weeks he had one severe attack and three milder ones.

On January 24th he came to Pittsfield by way of Boston. Just before leaving Boston pain came on again and caused him intense suffering during the journey. There was no hypodermic syringe at hand, and he felt only slight relief from the inhalation of chloroform. Soon after his arrival he was relieved by morphia, but the pain returned and continued for more than twenty-four hours, requiring morphia again on the following day. On that day the temperature was normal and pulse 80° to 100° . There was tenderness over the region of the gall-bladder and pain there, and also below the right scapula. No increased dulness or other indication of a distended gall-bladder, and no enlargement of the liver; urine very dark brown; skin deeply jaundiced.

On the third day the pain was less, but the temperature rose to 101.5° , and pulse to 108° . On the fourth day, a sharp attack of pain came on with nausea and

vomiting. He was again relieved by morphia. After this there was no more severe pain, but tenderness was great for three days longer. During the week he had taken almost no food, and for a week after he took only liquid food in small quantities.

The patient was now told that surgical interference could no longer be deferred with safety, and readily consented to the operation. It was decided that this should be performed by Dr. William T. Bull, of New York, at the House of Mercy, in Pittsfield, on the 15th of February.

On the morning of the 13th he took a dose of Carlbad salts which caused two dejections, soon after which he was again seized with pain which lasted all day, with excessive tenderness and vomiting. The next day he was free from pain, but had slight tenderness and occasional nausea. Pulse and temperature normal.

On Sunday morning, February 15th, he went to the House of Mercy, where cholecystotomy was performed by Dr. Bull, who has kindly furnished me the following description of the operation:

"A four-inch vertical incision over the cartilage of the ninth rib exposed the abdominal cavity. The gall-bladder was not prominent, but was easily brought into view by wedging the adjacent intestine out of the way with flat sponges. It appeared to be constricted about its middle. The fundus was aspirated and two drachms of bile removed. It was then opened, the wound held apart with artery clamps; a soft bougie and also a probe was passed through the constricted body, and was arrested by a calculus which could be distinctly felt with the finger. It could be moved to and fro, a distance of two inches, apparently in the dilated cystic and common duct. The structure was overhung by the duodenum, and united to it by such firm adhesions that I could not separate them without fear of tearing the wall of the intestine. In consequence of this adhesion, the finger felt the calculus through the wall of the duodenum, when it was pushed in the lowest position it would occupy. When it was forced into its highest position it was close against the under surface of the liver, and the part of the duct it occupied appeared to be free from the duodenum. It was difficult in the field of operation to determine the precise limits of the duodenal wall. In making the incision to remove the calculus the wall of the gut was incised for a distance of half an inch where it lay over the duct. The wound was closed with a continuous catgut suture through the mucous coat, and outside this interrupted Lembert sutures.

"The incision in the wall of the duct was left open, a rubber drain inserted in it, and the edges of the incised gall-bladder sutured with catgut to the parietal peritoneum. The viscera was not long enough to permit the skin to be included in this suture. The drain was surrounded with tampons of iodoform gauze and the abdominal wound closed by silk sutures about them and the tube."

Duration of operation two and one-half hours, chloroform was the anesthetic.

The calculus was oval, of the size and shape of a nutmeg, and weighed 55 grains. Its longer diameter is $1\frac{1}{8}$ inch and its shorter diameter $\frac{3}{8}$ inch.

This operation was beset with unusual difficulties, for the following reasons:

(1) The gall-bladder was hidden behind the intestines and liver, and when found was contracted and contained no calculus.

(2) The calculus was in the dilated duct, was hidden behind the duodenum, and united by firm adhesions to the surrounding structures.

(3) The operation was protracted by the necessity of sewing up the incised duodenum.

(4) Owing to the deep position of the gall-bladder and duct and to the adhesions which held it there, the incised edges could not be accurately stitched to the abdominal wall, as is usually done, and the danger of the escape of bile into the peritoneal cavity was great.

After the operation the patient was greatly prostrated. In the evening he had a pulse of 108, temperature 98° and respiration 36. For four days following, the pulse, which was feeble, ranged from 120 to 150. Temperature 100.4° the second day, and 100.2° the third day, after which it was nearly normal. On the second day the urine contained albumen one-tenth of its volume, but this disappeared on the third day and did not return. He suffered from severe pain in the wound and whole of right side, and required hypodermic injections of morphine during the first few days. For forty-eight hours he took nothing by the mouth. On the third day he took champagne and on the fourth day he began to take peptonized milk. From the first he had enemas of peptonized milk, afterwards alternated with beef-juice.

The bile was discharged very copiously. For three days it was very watery and pale, being mixed with serum. After this it was thicker and bright yellow. The dressings were changed at first twice a day, but it was soon necessary to change them every eight hours and afterwards more frequently, sometimes every two hours. Great masses of absorbent cotton were completely saturated, as well as the bandage, clothing and bedding. This inflamed and excoriated the skin and caused great suffering. It caused him such pain to be moved that the dressing became a very difficult matter. The bile escaped around the tampon and not through the tube.

On the eighth day the sutures were removed. The wound had then healed, except where kept open by the tampons. The bile flowed chiefly from the lower angle of the wound and not through the tube. It was yellow and green, with much watery fluid, and the skin was inflamed wherever touched by the wet dressings and clothing.

With the discharge appeared a few white specks which, on examination, proved to be milk-curd. It was therefore evident that the wound in the duodenum was not united, and that its contents were escaping.

The three tampons surrounding the tube were removed on the eleventh, twelfth and thirteenth day. A cavity was then left, two inches in diameter and two inches deep, lined with healthy granulations. The tube was removed and found to penetrate one inch deeper than the bottom of this cavity. The tube was not obstructed. It was cleansed and replaced and surrounded with tampons. The bile, however, continued to flow out around the tube until March 7th, the twenty-first day, when additional fenestrae were cut close to the inner end of the tube and the cavity was packed very tightly with gauze. After this the discharge came chiefly through the tube.

The discharge from the duodenal fistula continued till March 14th, four weeks after the operation. For one week longer, bubbles of gas escaped during the dressing, and after this the fistula remained closed.

As long as nothing but milk and liquids were taken by the mouth, the discharge from the fistula was very

watery. It was at first acid in reaction, but afterwards neutral; but it was excessively irritating, and excoriated the whole side and back. It never contained more than a few small particles of curd, though very large quantities of milk were taken. The caseous mass passed onward through the duodenum, while the watery portion poured freely out from the fistula. When solid food was taken the discharge from the fistula was genuine chyme.

When the tampons were removed, as they were daily, the cavity surrounding the tube would immediately fill with half an ounce or more of bile and food. The bile came from the right side of the tube, and the food from the small orifice at its left side. As soon as this was withdrawn by a syringe it would well up again from the bottom. The amount of bile was amazing, but it could not be measured.

The wound granulated rapidly, and on March 26th, five and a half weeks after the operation, had closed firmly about the drainage-tube. This was then removed and a smaller one substituted, which was kept in for two weeks longer. On April 4th, seven weeks after the operation, the discharge of bile ceased for a time, and bile was then first seen in the stools. Bile was occasionally discharged from the tube, however, until April 18th, after which no more was seen. This was nine weeks after the operation. When the flow of bile was first checked, pains would be felt like the premonitory pains of his former colics. When bile reappeared at the wound, the pain ceased. A slight serum oozing continued till May 13th, since when there has been no discharge of any kind.

The stick of nitrate of silver was occasionally used to facilitate the closure of the sinus. The granulating surface was liberally dusted over daily with aristol, which acted admirably. For the protection of the skin, ointments were at first used, such as lanoline and zinc ointment; but the dry application of bismuth was found more comforting and healing. Tampons of wool were found better than cotton or gauze, as by their elasticity they kept the bile out of the wound and forced it to flow through the tube.

The bowels were at first obstinately constipated. Repeated enemas were given, as well as salines by the mouth; but nothing came away except the débris of the nutrient enema until the twelfth day, after which the stools were liquid and dark-colored until the twenty-first day, when the first milk-curd appeared in the stools. These were colored till the twenty-sixth day, after which they were nearly white in color and very copious till the forty-ninth day, when the normal color returned. There was therefore no movement from the upper portion of the bowels for three weeks, owing in part, no doubt, to the escape of the liquid portion of the food, as well as to the morphia which had to be given to a greater or less extent during that period.

No periodicity could be discovered in the discharge of bile; but the duodenal discharge varied with the feeding. It was constant as long as liquid food was taken at short intervals; but when regular meals were taken, it came in floods about an hour after meals.

For the first two weeks the patient was unable to turn himself in bed. At the end of four weeks he sat up in bed, and at the end of six weeks was walking about the hospital. He became greatly emaciated during the first four weeks, while the duodenal fistula was open, but began to gain flesh as soon as this was closed.

The jaundice began to fade immediately after the operation, and at the end of six weeks had all disappeared except a slight yellow tinge upon the abdomen.

I went out of town on the 1st of April, six and a half weeks after the operation. He was then wearing the small tube, but was up and dressed. Dr. F. K. Paddock took charge of him during my absence. On my return on the 13th of May, Mr. B. met me at the station, looking well and very happy. Since then he has been well, though not very strong. He has had regular bilious stools, no pain, no jaundice and has gained flesh.

**A CASE OF TOTAL OBLITERATION OF THE
ESOPHAGUS THROUGHOUT THE GREATER
PART OF ITS COURSE, OF DOUBTFUL
ORIGIN; EXTERNAL ESOPHAGOTOMY AND
ATTEMPTS AT DILATATION; DEATH.¹**

BY MAURICE H. RICHARDSON, M.D.,
Surgeon to the Massachusetts General Hospital.

G. C., three years of age, was sent to me at the Massachusetts General Hospital by Dr. George H. Francis, of Brookline, on July 1, 1891.

Family history good. The child was perfectly well until last January, when he began to have difficulty in swallowing food. At first solids, and then liquids, were with difficulty kept down. He could swallow liquids, but they were immediately regurgitated. At other times he could swallow and keep them down. This state of things has continued to the present time. One day nourishment will not be retained at all, and the next day perhaps several quarts of milk will be swallowed and kept down. The child is emaciated and restless, otherwise not remarkable. At this time there was no history given of any possible local cause, such as the accidental swallowing of any burning or other irritating fluid.

On the 21st of July, having been under observation three weeks and no material change having taken place, he was discharged on account of an outbreak of scarlet fever in the ward.

On the 27th of July, 1891, he was re-admitted. Since leaving the hospital the little boy has not been able to swallow anything. Re-enters very emaciated and with a feeble and rapid pulse. Put at once on nutrient enema and inunctions of cod-liver oil.

On the 29th, under ether anesthesia, an incision was made in front of the sterno-mastoid muscle on the left side, and the osophagus was quickly exposed just below the level of the thyroid cartilage. At this point it was normal in appearance and in calibre. The sides of the incision were grasped with retractors, and the canal exposed down to the level of the sterno-clavicular articulation, where a firm, fibrous stricture was encountered. It was impossible to find an opening into this stricture with the smallest urethral instrument. At one time it seemed as if a passage had been found, and through this was passed a filiform bougie. The opening was gradually dilated until it would admit the end of a small gum-elastic catheter. After very careful manipulation, the instrument was passed into what was thought to be the stomach. It was noticed immediately that air entered and was expelled from the mouth of the catheter with the movements of respiration.

It seemed probable that this was air passing to and from the stomach. After very careful observation of this unexpected phenomenon, a small quantity of milk and brandy was injected through the catheter into what was supposed to be the stomach. The child did not rally well after the operation, and died that same afternoon.

At the autopsy it was found that the esophagus had become entirely obliterated, from the level of the sterno-clavicular articulation to the cardiac orifice. It was impossible to pass any instrument whatever through the canal. The catheter had made a false passage to the right into the pleural cavity into which the milk and brandy had been injected.

This very unusual case presents certain features of great interest. It did not seem to me possible that this could be a congenital stricture of the esophagus, because the onset had been quite sudden, and there had been no history of difficulty in deglutition up to the third year of the child's life. I therefore, some time before the operation, investigated the possibility of the closure being due to some corrosive action. I made careful inquiries, but was unable to find any ground for the belief that the child had swallowed anything injurious. Nevertheless, I did find that the first attack came on suddenly.

The operation demonstrated clearly the feasibility, in children, of exposing esophageal strictures situated five inches below the level of the incisor teeth. The upper end of the stricture was brought into view with the greatest ease. It was possible to hold back the sides of the osophagus and to search for the upper orifice without any difficulty whatever. In spite of all the care that I could use in the passage of bougies and in the introduction of the catheter, the false passage was made. It would be impossible to use any force whatever in dilating a supposed stricture without the greatest danger of making a false passage. Unless the eye of the surgeon is upon the point of the instrument so as to guide it with absolute knowledge, the slightest force is sufficient to cause a lateral deviation into the pleura or into the posterior mediastinum. I was not conscious at any time of using any but the very gentlest manipulation.

In a case of this kind there is little to regret in the fatal termination. The only other course would have been a gastrostomy. I think no one would advocate such an operation in a child of three. Life, certainly, would not be worth living were it necessary always to employ this means of feeding.

I would advocate the use of external esophagotomy for the relief of annular strictures situated within reach of the finger after an opening has been made through the neck. It is quite possible, as I have already shown, to reach with the finger as far as the arch of the aorta. I do not believe that it is justifiable to attempt any radical dilatation of benign strictures situated within reach of the finger, without first exposing the parts by the external incision. No degree of force sufficient to dilate thoroughly a stricture can safely be used through the mouth. In the case of this child, had I found a narrow stricture, I should have been tempted to excise the ring and unite the ends of the tube in a manner similar to that used in circumferential enterorrhaphy.

One other point to be noted is the importance of operating early. I have no doubt that in this case the chances of recovery were greatly diminished by the

¹ Read before the Boston Society for Medical Improvement, November 23, 1891.

four weeks' delay which I employed in studying out the case. During that time the child failed very much indeed. Although I do not believe that it was possible for this child to recover under any circumstances, yet had the conditions been otherwise, I am confident the delay would have had an unfavorable influence on the result.

Clinical Department.

A CASE OF HYDROPHOBIA.¹

BY GARDNER C. PIERCE, M.D., OF ASHLAND, MASS.

ABOUT seven o'clock on the morning of July 14, 1891, three children living in the south part of the town of Ashland, Mass., were savagely bitten by a Scotch collie dog weighing about sixty pounds, who seemed to be "running amuck" in attempting to bite every one he met in his pathway. He evidently was the same dog that bit a man in South Framingham about five o'clock on the same morning. Counting each tusk hole and each tusk laceration a bite, we found that Lizzie, aged eleven, was bitten in three places; Mollie, aged seven, was bitten in twenty-one places; and the little brother Myron, aged five, was bitten in nineteen places. Of these three children Lizzie, the oldest, presented only two bites on the left arm above the elbow, and one bite on her left cheek. Mollie, who was used the worst, presented severe wounds and lacerations on both legs below the knees; for she and her little brother were barefooted when attacked. The boy Myron also had very ugly wounds on his legs and left arm. On these two younger children about half of the bites consisted of a tusk hole from one-third to two-thirds of an inch deep, and the other marks of violence were deep tears or lacerations anywhere from one inch to two inches long. Some of these fissures were so deep that the flesh rolled out, presenting ragged, ugly, gaping wounds.

The patients were seen by the writer about thirty minutes after the attack of the dog. The wounds were cauterized with a thirty-three per cent. solution of carbolic acid. The father was advised to take these children to the Pasteur Institute in New York for treatment, immediately; for the dog was presumed to be rabid. The most certain way of ascertaining whether or no the dog was rabid, would naturally have been to have caught and placed him in confinement. But he was in altogether too dangerous a condition to allow of this. He evidently was laboring under an extreme degree of delirious excitement, and was ready, and even eager, to attack and bite every living thing that came in his way. After his attack on the children he made a fierce onset upon a teamster in the yard of the Adams farm, whereupon he was beaten to death with clubs by the attendants about the place. The animal was buried without the writer having an opportunity of seeing the body. But those who did see it, said he was quite thin of flesh. They opened his stomach, and found in it a dozen or more gravel-stones about the size of cherry pits, perhaps two tablespoonfuls of road-dirt, some grass, and some pieces of biscuit. Before he was killed he was frothing, they said, at the mouth and "furiously excited." All these circumstances seemed to indicate that the animal, without doubt, was rabid.

Just forty-eight hours after these children were bitten, they had reached New York, and had taken their first inoculation at the Pasteur Institute. The special methods in this treatment are well understood by us all, and need not be described here. These children were treated by what we would understand as the *simple* Pasteur inoculative method. The inoculations or injections were practised once each day. The term of treatment continued eighteen days. During the treatment the patients had no particular symptoms of any kind. On Saturday morning July 31, the children received their last and eighteenth inoculation, and the same day started for and reached home at eleven o'clock at night.

On the Tuesday morning following (August 4th.) Lizzie, the oldest girl, was taken ill with nausea and vomiting, and was quite feverish and restless. Her nausea and vomiting continued until the next day, when she began to improve, and by the night of August 5th was well again. She had no physician to attend her. What was the nature of her indisposition, cannot be known. Whether a recently inoculated person can present incipient symptoms of the rabid state soon recovered from, is not now exactly known; but it is something to be looked for in future observations.

The next day after Lizzie recovered, Thursday afternoon, August 6th, and five days after he had taken his last inoculation at the Pasteur Institute, Myron, the little five-years-old victim, was also taken sick. His first symptoms were moderate feverishness, nausea and vomiting. There was a slight degree of headache in his demeanor. Friday, the next day, the nausea and vomiting continued. He was chilly and feverish by turns. His face was alternately flushed and pale. A physician thus far had not been called to him, for the parents supposed he was probably sick like his sister, and would soon be well again. But Saturday morning, as he appeared much worse, the writer was summoned, when he noted the following symptoms: Temperature 100°, pulse 105. The pupil of the left eye was considerably dilated. There was a constant twitching at the angles of the mouth, and a slight jerking of the fingers of both hands from a spasmodic action of the muscles of the forearms. The tongue was slightly coated. He did not complain of headache. To a close observer a slight, but somewhat peculiar staring expression was noticeable in his eyes. His countenance for the most part was pale. By Saturday afternoon he was delirious at times, but in the intervals was quite rational. The stomach at this time could not retain much food or drink. He had much difficulty in swallowing liquids, yet could force some down after much effort. His eyes were sometimes bright and glistening, and at other times they appeared dull and expressionless.

On Sunday morning the patient was much worse in every way. All of the symptoms had increased in intensity. The temperature, however, was only 100.5°, but the pulse was 130 per minute. The skin would be flushed for eight or ten minutes, and then for about the same length of time be quite pale. An eruption appeared on the front part of the body, and on the left cheek, — more marked in these localities, but also faintly to be seen on the back and other parts of the body. It had somewhat the appearance of urticaria, but the patches were larger. Some were crescentic in shape, others were oval, while others were of irregular outline. For a few minutes — perhaps ten or

¹ Read before the Framingham Medical Society, November 3, 1891.

fifteen — they could be seen in full figure, plain and distinct ; and then they would disappear entirely, leaving the skin pale and somewhat dusky for about the same length of time, and then reappear, and so on repeatedly until the time of his death. The pupil of the left eye still continued dilated. During the intervals while the child was rational, his eyes and entire physiognomy wore a peculiar apathetic, mingled with a surprised and dumfounded expression difficult to describe and never to be observed in any other disease. At other times he was very delirious. He was exceedingly restless and wanted to be moved from one bed to another, and from one room to another frequently. His skin was exceedingly hyperesthetic, and to be fanned was unbearable. Any breeze or gust of wind blowing on to the bare skin would cause him to make complaints.

During the thirty-six hours preceding death he grew emaciated to a marked degree. Sunday, as the day advanced, the difficulty in swallowing increased. He was very thirsty ; and, craving water, would seize a cupful with great eagerness ; but the attempt to drink was invariably prevented by severe spasms in the throat. So he became hydrophobic, not because he did not want water, but because he did not dare to try to drink it. Another symptom noticed was a peculiar sound occasionally coming from his throat of a croaking character almost like a prolonged hiccup. It undoubtedly was produced by a synchronous spasm of both glottis and diaphragm.

Throughout the day, on Sunday, a thick viscid phlegm or saliva was continually collecting in the mouth and throat, and frequently had to be removed so the patient might breathe. As night approached, this secretion increased rapidly in quantity. About sunset a frothiness was continually appearing from the corners of the mouth and had to be wiped away almost continually. It was not noticed that his legs were paralyzed, as they sometimes are in the last stages of this disease. By seven o'clock P. M. he was weakening rapidly, and his throat filled with its secretions in such quantity, that it seemed impossible to keep this passage clear. He was continually delirious from eight o'clock until ten, when he passed into a comatose state. The twisting of his mouth and hands increased. He had no general convulsions, as is sometimes the case in this disease, but undoubtedly would have had, if he had lived a day longer. The patient died at quarter-past eleven Sunday night, partly from exhaustion, but more especially from asphyxia caused by spasm and the viscid secretions in the throat.

In the clinical history of this case the two most noteworthy symptoms were the hydrophobia and the aerophobia. These two characters are competent to prove in this patient's sickness, without the shadow of a doubt, the diagnosis of hydrophobia. Dr. James Boynton, of South Framingham, was called in to see the patient Sunday afternoon, and agreed that the case was one of hydrophobia.

The question now arises among the laity of this neighborhood, and very reasonably among physicians also, what cause, in this particular case, produced the hydrophobia, — the bite of the dog or the Pasteur treatment.

No physicians hereabout claim to be experts in rabies lore ; but, if Pasteur had been here, he perhaps would have inoculated rabbits in the usual way with the virus taken from the medulla or spinal cord of this child,

and then if they developed rabies after a period of incubation of *seven* days, it would have proved that the treatment caused the boy's death ; but if the disease supervened after an incubation of *fifteen* days, it would have shown that the *dog-bite* killed him. The trouble hanging about this attempt to prove causes, involves the fallacy, that in coming to the crucial, practical test, Pasteur substitutes a *boy* for a *rabbit* ; and, as a result, the incubatory conditions may be much changed by having the virus pass through the human subject.² So the above test is not conclusive or satisfactory.

With the existing limitations to our knowledge in this direction, for the present, our decision as to the safety and advantages of the Pasteur treatment must rest on the results given by thoroughly tabulated and well attested statistics. Statistics seem to prove that the death-rate under Pasteur's treatment is a little less than one per cent. ; while the mortality in people bitten by rabid animals and not inoculated, amounts to fifteen per cent. at least.³ The above statistics were made by a physician in Paris, who is not in any way connected with the Pasteur Institute. Other investigators have given non-treated cases a much higher mortality rate.

Now, if the Pasteur treatment is liable to produce rabies, then this fifteen per cent. of deaths among non-treated cases inevitably will be increased by the alleged dangers of the treatment *itself* ; so that the statistics would, under this supposition, show a larger percentage of deaths *under* treatment, than it would *without it* ; which is, we well know, not the case. Furthermore, it is claimed, that nearly all the physicians and attendants connected with the Pasteur Institute in Paris have been inoculated, and none of them ever suffered any harm from the procedure.

The all important question arises : What will you do, if there is brought to you a person, who has just been bitten by a rabid animal ? The writer of this paper would send him to the Pasteur Institute immediately. But in the face of this assertion, at a medical meeting held somewhere here in New England, there was put to vote this question : Will you send your cases bitten by rabid dogs to the Pasteur Institute for treatment ? A very few physicians voted "Yes" ; a very few voted "No" ; and quite a majority did not vote at all. The result of this vote shows that this question is far from being settled in the minds of our medical men even at the present time, and is still a subject worthy of much further consideration.

EXTRA-UTERINE PREGNANCY; CELIOTOMY; RECOVERY.

BY F. W. JOHNSON, M.D.,
Visiting Gynecologist, Carney Hospital; Visiting Gynecologist, St. Elizabeth's Hospital.

G. F., married, aged twenty-eight, consulted me, Tuesday, September 29, 1891. A diagnosis of extra-uterine pregnancy was made, and I operated on her the next day at the Carney Hospital. The following is the history of the case and the result of the examination :

Dysmenorrhœa since puberty. The pain, situated in front and low down in the abdomen, comes on several days before the flow and lasts throughout menstruation. For the past year has had quite severe pain in

² Boston Medical and Surgical Journal, April 1, 1886, p. 299.

³ Braithwaite's Retrospect, page 20, January, 1890.

the right ovarian region when unwell. Flows five days. Flows quite freely. Leucorrhœa for years. Always been regular to the day until August 9th. Instead of menstruating at this time, she went to August 16th, just one week over her time. August 16th flowing begun and continued, at times profusely, for two weeks. In two weeks the flowing again began, and has continued up to the present time. Since August 16th, when the flowing began, until September 20th has had a dull pain in right ovarian region. The breasts have enlarged. Sunday, September 20th, was suddenly seized with severe cutting pain in right ovarian region. This pain lasted one hour, and produced fainting. This severe pain was repeated September 28th, and lasted two hours. Formerly the pain in the right ovarian region was dull in character, but since the severe attack of pain it has been more cutting in character. From August 9th to August 16th, the week following the date of expected menstruation, there was dull, heavy dragging-down in lower abdomen.

Examination. — From half-way between umbilicus and pubes, extending over the whole of the lower part of the abdomen, there was marked sensitiveness on pressure. By vagina, a soft mass, the size of the fist, excessively sensitive, was found in Douglas's pouch, and on this the uterus rested in a position of retroversion. Bright red blood flowed from the cervix. Uterus measured three inches in depth. Temperature 99°; pulse 110.

Operation. — Dr. Holder assisted. Drs. Conant, McQueeny and Storer were present. On opening the peritoneal cavity, dark-colored blood welled up through the incision. The abdominal cavity below the incision contained fluid and clotted blood of a dark color, and no bright blood was found until the right tube and ovary were brought into view. A portion of the right tube towards the ovary was found dilated. This dilation was about the size of a small English walnut, and from the upper part of it fresh blood oozed out through an opening the size of a pin's head. The right tube and ovary were ligated and removed. On the left side a cystoma of the ovary was found, and it, with the tube, was ligated and removed. The peritoneal cavity was thoroughly washed out five times with a saline solution, and the abdominal wound closed with silk. Silk was used, as my supply of silver wire had been exhausted on a laparotomy done two hours before. About a quart of fluid and coagulated blood was removed. The mass in Douglas's pouch was composed of coagulated blood, and was dug out with the fingers. Sutures removed on the eighth day. Convalescence was uninterrupted.

Twenty-three days after the operation she was discharged well. December 2d, she reported that she felt perfectly well.

My first case of extra-uterine pregnancy was operated on November 26, 1877. Rupture took place at the Globe Theatre. The patient gave a "loud scream, and fell to the floor unconscious." She was carried home in a carriage, and after a few weeks' stay in bed was able to be about. Though an old patient of mine, I had not seen her until she got about. On examination, a mass as large as a cocoanut was found posterior to the uterus. This mass felt hard, somewhat elastic and non-fluctuating. Cæliotomy was done, and an intra-peritoneal hematocoele found. The coagulated blood was walled off by adhesions between intestines, omentum, tubes and broad ligaments. On the right

side the appendix helped to make part of the wall. Both tubes and ovaries were removed and the abdominal cavity cleansed of blood. Drainage-tube inserted. The pathologist was unable to find anything in the mass of blood and débris that would point to a rupture of an extra-uterine pregnancy as the source of the intra-peritoneal haemorrhage.

Dr. Whitney's Report. — "The following is the description of the ovaries and tubes from the case of Mrs. G. F., received from you, October 1, 1891:

"(1) Ovary and Tube. The portion of the tube measured about six and one-half centimetres. About two centimetres from the fimbriated end, which was normal, was a rounded enlargement measuring about two and one-half centimetres by two centimetres, dark red in color and covered with shaggy, thin adhesions. About the middle of the nodule opposite the side of the ligament was a very small rent with a hemorrhagic infiltrated edge. The remainder of the tube, about two centimetres, was of normal size and calibre. Sections made through the nodule, and examined microscopically, showed the greater part to be made up of blood clotted among small villous projections, fibrous in character, and covered with a low epithelium, similar in every way to the villi of an immature placenta. Just beneath the outer surface were large and very thin-walled vascular sinuses. The cavity of the tube was dilated, and its lining membrane was apparently reflected up on to the mass of blood and villi: but whether it was continuous entirely over it, could not be determined. Apparently, however, it was not. From the distal end of the nodule there opened a distinct diverticulum from the tube, which could be followed almost to the fimbriated end, where it stopped. The relations were such as to show that the nodule had developed entirely in the main tube, and not in the diverticulum. In none of the sections was there any evidence of a fetus found. The ovary attached to this tube measured two by two and one-half centimetres, was irregularly shaped, and from one place a reddish nodule projected, which, on section, showed an irregularly festooned outline enclosing a yellow mass of large cells (corpus luteum).

"(2) Tube and Ovary. The piece of tube measured about six centimetres, and was of normal size and structure. The ovary measured about three by four centimetres, and was mostly made up of a cyst, filled with thin fluid, extending deeply into the hilus, where there was a layer of ovarian tissue gradually thinning out over the cyst.

"The case is one of tubal pregnancy, with rupture. There are no positive data as to the length of time, but from its size it is probably within two months."

THE TITLE OF M.D. IN ENGLAND. — A case of interest to the medical profession in England has recently been decided by the court of Queen's Bench. The defendant having the right to practise in England by the degree of L.S.A. only, publicly described himself as an M.D. on the strength a degree issued by the Beach Medical Institute of Indianapolis. It has been decided that the possession of a degree not registrable in England is not sufficient to justify the holder in describing himself by the title of the degree for the purpose of obtaining practice, even if he has already the right to practise by virtue of some other degree.

Medical Progress.

REPORT ON PROGRESS IN OBSTETRICS.

BY CHARLES M. GREEN, M.D.

MATERNAL IMPRESSIONS.

EVER since the appearance of a paper on this subject by Fordyce Barker, not long before his lamented death, the journals have furnished numerous instances, apparently well authenticated, of the effects on offspring of startling impressions on the mother. It is not easy to explain away on the "coincidence" theory these evidences of marked physical impression during pregnancy: nor again is it easy to understand how these impressions occur, nor why they do not occur oftener, if at all.

Herr¹ (Ottawa, Kan.) reports two authenticated cases, one quite recent in his own city: a lady six weeks' pregnant was summoned to court, and was interrogated by a justice who had cleft palate. The woman was much frightened and for weeks this experience was present in her mind: her child was born with a deformity identical with that of the justice. In the second case, a pregnant woman was frightened by a frog which had been purposely placed behind her chair: she fainted when she saw the frog, and her child was born with a head which was said to be "the exact image" of the frog's. [Was it simply a species of anencephalus?]

[One case has occurred to the writer, in which a pregnant woman was startled by a rat on going down a flight of stairs in the dark: her child was covered as to its back with a growth of soft, brownish-gray hair, resembling that of the common rat, which did not disappear as the child grew out of infancy. The question is occasionally raised, apropos of the physical defects and deformities which are so frequently reported as the result of maternal impressions, why physical beauty may not be imparted to offspring by suitable influences thrown about the mother: it is quite commonly believed among certain circles of the laity that such a result is possible. Medical science has not lent itself to any extent to the solution of these psychophysiological questions; but the future may have much in store for those interested in the prosecution of inquiries in that direction. — REP.]

STRYCHNIA AND THE HOT DOUCHE IN THE PROPHYLAXIS OF PROTRACTED LABOR.

Ferguson² (Toronto) recommends the administration of strychnia in the latter part of pregnancy with a view to improving the muscular tonicity of the uterus and thereby shortening the duration of labor: incidentally the drug is known to act as a bitter tonic and as a corrigent, to some extent, of intestinal inactivity so common in pregnancy. Ferguson gave strychnia to one hundred gravide whose previous labors had been protracted owing to uterine inertia and irregular, crampy pains: primiparae were excluded. The hundred cases treated with strychnia had an average of nine hours of labor; whereas the average duration of previous labor in the same hundred women was seventeen hours. He found that the uterine tonus was much improved by the course of strychnia, the contractions being longer and more regular: he also observed that

better contractions ensued in the third stage, that after-pains were greatly lessened, and the amount of hemorrhage reduced. The dose employed varied from one-sixtieth to one-thirtieth of a grain three times a day: one patient had one-sixteenth of a grain thrice daily, her two preceding labors having been characterized by almost complete uterine inertia. No ill effect was observed in any case.

[The reporter has for some years been accustomed to give thrice daily during the last two months of pregnancy, to all but apparently strong and robust women, one-fourth of a grain of extract of *nux vomica* combined in pill with one grain of Querenne's iron. No observations have been made by him with reference to the possible shortening of labor by this treatment; but there has been no question but that patients have been generally benefited thereby. Ferguson's experiment is an interesting one, and his recommendations worthy of trial. Certainly very many gravide are much benefited by general tonic treatment, and those of flabby muscular fibre ought to have a better labor under the stimulating influence of strychnia. It is perhaps needless to add, however, that too much reliance must not be placed in drugs alone, but that attention should be directed to nutrition and general hygiene: poorly nourished muscles cannot effectively respond to any stimulus. — REP.]

Ferguson also recommends the use of a two gallon vaginal douche twice a day for a week or ten days prior to labor, as a means of softening the cervix in primiparae and in those in whom previous tedious labors have been known to be due to rigid soft parts: he recommends that the water should be 105° to 110° F. hot, and that the hydrostatic pressure should be only sufficient to cause the water to flow. Used in this way he has never known the douche to induce labor prematurely.

THE TREATMENT OF POST-PARTUM HÆMORRHAGE FROM TEARS OF THE CERVIX.

While haemorrhage from the smaller vessels in the cervix may be controlled by hot vaginal douches or by gauze tampons with or without styptics, tears of the uterine artery or one of its large branches give rise to bleeding which soon proves alarming unless the torn vessels are secured by suture. The operation of repairing a torn cervix post-partum is not a difficult one, especially since it is easy with vulsellæ forceps to draw the uterus down to the vaginal introitus, where the sutures can be introduced by sight. But if the attendant has not the means at hand for properly repairing the tears, and wishes to control the haemorrhage while waiting for assistance to arrive, it is useful to remember that traction on the cervix with a suitable forceps will accomplish the desired result.

Parsonow³ (Stettin) reports a case in which this fact was clearly shown: called to the assistance of a colleague he found that for over two hours the latter had controlled serious haemorrhage from a torn cervix by bimanual pressure; but on the least cessation of pressure the bleeding was shown to be unchecked. Parsonow seized the cervix with toothed forceps and drew it deeply down, when the bleeding at once ceased: sutures were then inserted and the tear closed. In other words, strong traction on the uterus puts the large vessels on the stretch and thereby efficiently occludes them.

A PLEA FOR FULL MECHANICAL DILATATION OF THE PARTURIENT CANAL BEFORE OBSTETRICAL OPERATIONS.

Under this title Abbott⁴ (New York) has called attention to an important obstetric procedure, which is too apt to be ignored or forgotten. It is commonly acknowledged that the cervix should be dilated by nature or art before delivery is attempted; but there is less appreciation of the desirability of a well-dilated vagina and perineum before the child is allowed to pass. Some writers indeed have recommended leaving the membranes intact until the vagina as well as the cervix is dilated: the younger Byford wrote in advocacy of such procedure. But in most cases the membranes rupture spontaneously when the os uteri is fully expanded.

Recognizing the necessity in some cases in which rapid delivery is indicated of extracting without previously complete dilatation, Abbott truly claims that except in such emergencies, complete dilatation of the entire canal should be secured before operating. The advantages of such dilatation are that more accurate diagnoses can be made, instruments can be more easily used, lacerations are less likely to occur, and there is less danger of serious compression of the fetal head and of uterine atony from exhaustion. Certainly it is as desirable to dilate the lower as it is the upper part of the birth-canal. The writer further points out that oftentimes when the head is arrested, complete dilatation under anesthesia stimulates increased activity in the expulsive forces and at the same time diminishes the resistance to be overcome; hence a labor will often terminate naturally which would otherwise have required artificial assistance.

The dilatation is easily accomplished with the hand, introduced with care in conical form and under most careful asepsis.

ANTIPYRIN AS A MEANS OF RESTRICTING THE SECRETION OF MILK.

Guibert⁵ (Montpellier) found accidentally on two occasions that after taking antipyrin at the rate of two grams a day, nursing mothers showed already on the second day a considerable diminution of milk secretion: after the antipyrin was omitted the milk returned to its former amount. He then tried the drug on nineteen cases, in seven of which the women had nursed several days, in the other twelve not at all: in each case he found the secretion was diminished. If the drug was continued for some days, the milk entirely disappeared.

SALT-WATER ENEMATA IN SEVERE POST-PARTUM ANEMIA.

The intravenous and subcutaneous use of salt solution has been found efficacious in severe anæmia post-partum; but in these forms of administration special instruments and skill are necessary. Heer⁶ has met with good results by introducing the solution per rectum,—a method easy of application and unattended with danger. In a case of severe hemorrhage following podalic version for placenta prævia, there was profound anæmia which did not improve after the usual treatment; and the radial pulse was not to be felt. About two litres of a lukewarm, one-half per cent. salt solution (one teaspoonful to the litre) were ad-

ministered per rectum, and the patient rallied with surprising rapidity, but collapsed again after a few hours. After a repeated enema of this solution, the pulse returned, the general condition continued improved, and the patient recovered in about a month.

Heer recommends in all forms of severe anæmia the rectal administration of salt solution as far superior to the intravenous or subcutaneous methods of application.

THE CARE OF THE BLADDER BEFORE AND AFTER LABOR.

Coe⁷ (New York) has a useful paper on this subject which deserves to be widely read. The article does not admit of sufficient condensation for this report; but a few points are worthy of especial emphasis.

The diplococcus found in the urine of puerperal cystitis is identical in form with that constantly present in the lochial discharge, and bacteria may reach the bladder by extension along the urethra, even when no catheter has been used: hence the prophylactic value of spraying or otherwise cleansing the external genitalia several times daily with an antiseptic solution. [A very good rule is to cleanse the vulva every time the pad or napkin is changed.] It is unnecessary to point out the probability of infection from the use of unclean catheters; but it is not fully realized that bacteria may be carried into the bladder, if the catheter is passed without previously cleansing the vestibule, and even then, if it is passed by touch. Garrigues has said "the old way of drawing the urine under the bedclothes was modest, but is irreconcilable with antiseptic midwifery." In short, he who would surely avoid puerperal cystitis must not only use a clean catheter, but must place it directly within the meatus by sight, the parts having previously been cleansed.

While the catheter must occasionally be used for various reasons, it is often employed simply because a woman cannot pass her water lying down. To overcome this inability, Skutsch has recommended that women acquire the art of urinating in the dorsal posture by practice in the latter weeks of pregnancy. Coe justly thinks this an unnecessary procedure, and has adopted the plan of allowing the woman who cannot micturate lying on her back to be supported in a sitting posture on a bed-pan in normal, uncomplicated cases. [This procedure would seem startling to many, until they remembered that among the poor this is a common practice. Unless a woman is very weak from long, exhausting labor, from hemorrhage or antecedent disease, unless there is some inflammatory complication or a torn perineum, and unless there is some cardiac lesion, there seems to the reporter no good and sufficient reason why a woman should not be assisted to sit up six or eight hours after labor long enough to pass her water. Many women can pass urine lying on the face or resting on the hands and knees; but if not, there would seem to be no adequate reason why, in uncomplicated cases, puerperae should not be allowed to sit up. Considering the risks of careless catheterization, such a plan is eminently preferable to a ready resort to the catheter. In a recent case of inability to pass urine on the back, the reporter allowed the woman to sit up with no untoward result. REP.]

PROFESSOR BARDELEBEN, of Berlin, on the fiftieth anniversary of his graduation in medicine, received from the emperor a patent of hereditary nobility.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

G. G. SEARS, M.D., SECRETARY.

REGULAR Meeting, Monday, November 23, 1891, the President, DR. FREDERICK I. KNIGHT, in the chair.

DR. J. H. MCCOLLUM read a paper entitled

THE SANITARY CONDITION OF BOSTON: A STATISTICAL PAPER.¹

DR. H. P. WALCOTT: Dr. McCollum's paper is most interesting, and has for its groundwork a body of vital statistics unequalled, for a city of the size of Boston, in this country, and not surpassed in any European State. It is probably well known here that the compulsory notification of cases of certain communicable diseases, which has existed for years here, has been introduced into Great Britain within the past two years only.

There is one apparent omission in Dr. McCollum's paper which I am inclined to criticise, and that is, the proportion of the number of children living, below five years of age, to the total population. I cannot help thinking that a chart, which recorded this proportion in connection with the other facts, might not show the curve so favorable to Boston as compared with Glasgow, which is observed in Chart III.

Though this proportion cannot now be ascertained for every year, it can be stated with reasonable accuracy for the years of the National and State census. I hope that this very valuable paper may be enlarged by some vital statistics of the sort indicated, because our public health authorities may in this way get some help to better methods of preventing excessive infant mortality.

DR. S. H. DURGIN: The paper is full of interesting facts, and it would be easy to conclude from a statistical point of view that Boston is in a good sanitary condition compared with many other cities. I suppose it is questionable as to how far we are justified in stating the sanitary condition of a city by its rate of mortality, and yet the fact that some relationship exists between the death-rate from preventable causes and the sanitary condition will not be doubted.

In looking over the death-rates of London to-day, I find that the percentage of deaths of children under five years of age to the total mortality has been gradually reduced from 44 in 1880, to 40 in 1889, while in Boston the percentage in the same class has been reduced from 38 in 1880, to 32 in 1890.

I wish I could present the comparative physical condition of Boston to you in as favorable light as Dr. McCollum has presented the statistical comparisons.

If we measure our present condition by the advanced standard of sanitary requirement, we shall find many deficiencies. It is only when we compare the present state of our city with that of ten or twenty years ago that we can see a steadily improving sanitary condition. It would require too much time to review all of these changes, some of which have been most satisfactory. It may be stated briefly that our sewerage system has been vastly improved and although not wholly finished, will soon be satisfactory to our own and neighboring cities.

¹ See page 49 of the Journal.

Our streets have been the subject of much discussion. They have been considerably improved in cleanliness and for practical use during the past year, and we can reasonably hope for greater changes as the subject becomes better understood by the City Council. Privy vaults and cesspools, which have been a constant menace to our people, are rapidly disappearing. The location, construction and care of stables are matters now dealt with under careful regulations and to the greater comfort of those who live about them. The high-tide levels, which were formerly of great annoyance and injury in parts of the city have been largely reduced by the construction of the intercepting sewer, which nearly encircles the city, but the ground-water line is still too near the surface in many parts of the city for the welfare of those who live on the lower grades. The tenement-house has been greatly improved in construction, adaptation and care, and yet a large percentage of the poorer class of the city are living in tenement-houses which are more or less overcrowded or otherwise unsuited for such occupancy. One great hindrance to a more rapid improvement in the tenement-house population is the lack of better but cheap accommodations, particularly in small isolated houses in the suburban districts, to which families may be sent from the crowded tenement-house.

DR. G. H. M. ROWE: I have but little to add to the subject of Dr. McCollum's paper. I have been extremely interested in the facts as given by him, and I think the paper is entitled to much praise. Like all statistical papers, it is one that should be studied by comparison in order to get at the deductions.

There is one suggestion that has been alluded to by Dr. Durgin, and that is, that the mortality is not always the proper guide for the number of cases of these various diseases. This has been notably exemplified at the Boston City Hospital. Some four or five years ago we rarely had a daily average of over forty to fifty cases of typhoid fever at the height of the typhoid season. Two or three years ago our daily average was between eighty and ninety, but this year, for six consecutive weeks, we have not run below ninety-five, and have had on a single day, one hundred and nineteen cases in the hospital. While the daily average number of cases has been very much larger, the death-rate has been much less than five years ago.

The opposite is true in regard to diphtheria. So far during the year we have had a much less number of cases than last year, and our mortality has been much higher. There are various ways of explaining this condition: the type of the disease and the stage in which it is brought to the hospital. The number of cases and the tables of mortality of the same sometimes go in opposite directions, as I have indicated. I believe it to be undoubtedly true that the laws in regard to compulsory notification in regard to contagious diseases are not carried out with the thoroughness that should be done. When this law is honestly and efficiently carried out, we shall then know much better of the true condition of public health in our community than we do now from the returns in the mortality of these diseases.

DR. J. B. AYER: Dr. Durgin referred to the disinclination of those in crowded parts of the city to live in the suburbs. It seems to me in the part of the city where I live there has been a great change in

that direction. Many of the families who lived there a few years ago now live several miles away from the State House. Perhaps they did not live in crowded houses, but several families in a house.

DR. GEO. B. SHATTUCK: Dr. McCollom's paper was so condensed and so full of important and interesting statements and figures that I may have missed some things, but I should have been glad to have had him give us a few more conclusions in regard to the subject. For instance, I should have liked his opinion with regard to consumption in reference to races, that is, some explanations in regard to the very high mortality in consumpti on here; whether our large proportion of Irish in the population accounts for it, and whether the number of that race in different wards bears any relation to the deaths from consumption. Of typhoid fever I see a great number of cases every year at the City Hospital. I never have had more than during this winter. In my service alone I have had pretty steadily an average of between thirty and forty cases, and that is only one out of three medical services. I have frequently heard the statement that a good deal of the typhoid fever is brought into Boston from the outside, and consequently I have taken an interest in the individual cases as far as I could to find out whether these people have been outside of Boston, and I find that in many instances they have not, that the disease probably originated in the city. Of course I am speaking of cases as they are seen at the City Hospital, and I should like to have had some conclusion as to whether the amount of typhoid fever was proportioned in any way to the wells and cesspools in the wards. I suppose a low rate of mortality in typhoid fever in a city is to be explained by a good water-supply and good drainage. The present perfection of those systems in Berlin, where much money has been spent, would be given as an explanation of the low rate of mortality from typhoid fever there. Certainly Berlin is a city where otherwise you would expect to have a good deal of typhoid fever. No doubt Dr. McCollom in summing up can give us some interesting conclusions in regard to these points.

DR. J. H. MCCOLLOM: In reply to Dr. Walcott's question I would say that it was impossible for me to obtain the requisite data from all the cities for estimating the percentage of deaths under five years of age to the living of that age for 1890. I agree with the gentleman regarding the importance of this percentage. The estimated number of living children under five years in Glasgow and in Edinburgh for 1890 with the percentage of deaths of children of this age can be found in the Annual Report of the Registrar-General of Scotland for 1890. In Glasgow, for 1890, the number of living children under five years of age was 72,636; the number of deaths was 5,780, giving a percentage of 7.96. The percentage of deaths under five years of age to the total mortality for the same year was 43.20. In Edinburgh, for 1890, the number of living children under five years of age was 33,258; the deaths were 1,899; the percentage was 5.71. The percentage of deaths under five years of age to the total mortality for the same period was 35.00. In these two cities it is evident that the percentage of deaths under five years to the total mortality bears a direct relation to the death-rate per one hundred of the estimated number of living children of this age. The accompanying table gives the number of living children under five years of age; the number of deaths under five

years; the death rate per one hundred, and the percentage to the total mortality in six cities for 1880. As this was a census year the number of living children in the American cities may be considered correct.

DEATHS OF CHILDREN UNDER FIVE YEARS IN BOSTON, NEW YORK, PHILADELPHIA, GLASGOW, EDINBURGH AND BERLIN, 1880.

Cities.	No. of Children under 5 yrs.	Deaths under 5 yrs. in 1880.	Per cent. Deaths to the Living	Per cent. to Total Mortality.
Boston	37,138	3,319	9.01	39.26
New York	140,387	14,650	10.43	45.00
Philadelphia	91,544	6,799	7.43	39.33
Glasgow	?	6,042	8.68	45.40
Edinburgh	?	2,138	7.60	42.85
Berlin	143,023	19,532	13.65	39.51

It will be seen from this table that a high percentage to the total mortality does not always indicate a high death-rate of children, as, for instance, Glasgow compared with New York. The percentage to the total mortality in the former city being 45.40 and the death-rate per one hundred of children under five years being 8.68, while in the latter city although the percentage to the total mortality is practically the same, the death-rate is 10.43. If Boston and Philadelphia are compared, it will be seen that, although the percentage to the total mortality in each of these cities is 39.00, there is a marked difference in the percentage of deaths under five years to the living of that age, the rate being 9.01 in the former city and 7.43 in the latter. If Berlin and New York are compared, however, there seems to be some relation between the death-rate under five years of age and the percentage to the total mortality. An increase in the death-rate coincides with an increase in the percentage to the total mortality in these two cities.

In reply to the question of Dr. Rowe, I would say that I have no doubt of the advantage gained by compulsory notification of cases of contagious disease. Of course all the cases are not reported because in many of these instances there is no physician in attendance.

In reply to Dr. Shattuck's first remark I have to say that, as a mere opinion based upon a very limited number of statistics, the children born in this country of Irish parents, are the most susceptible to consumption; that the young Irish immigrant comes next; and that the German immigrant is the least susceptible. The following tables give the deaths from consumption in Boston for 1890 with the nativity of the parents. These figures would be much more valuable if the number of the living of each nationality was given.

DEATHS FROM CONSUMPTION IN BOSTON, WITH NATIVITY OF PARENTS, 1890.

Nativity.	No.
United States	237
Ireland	796
England	37
Scotland	11
Germany	41
British Provinces	91
Italy	11
Other Countries	129
Mixed	78
Unknown	73
Total	1,496

The comparative immunity of the Italians is an interesting fact. Coming from a warm and invigorating

climate we should naturally suppose that they would be extremely susceptible to this disease, when, as a matter of fact, it is not so prevalent among them as among the Scotch and the English. As the number of Italians in Boston is nearly three times as great as that of the Scotch or of the English some idea of the relative frequency of this disease in these nationalities may be gained from the table. In reply to Dr. Shattuck's second remark, I have to say that typhoid fever has not been most prevalent in the localities where vaults exist. There are so few vaults in Boston, at the present time, that they could not be very important factors in the causation of this disease. The difference in the ratios of Wards 6 and 7 may be explained by the fact that there are more immigrants arriving in the former ward than in the latter. The newly arrived immigrant is particularly susceptible to this disease.

DR. R. W. LOVETT read a paper on,

THE TREATMENT OF CHRONIC SPRAINS OF THE FINGER-JOINTS.²

DR. W. P. BOLLES: I have been much interested in Dr. Lovett's paper as he has treated of a class of cases that occur pretty commonly in surgical practice, and yet are not adequately noticed in the text-books. The pathology is undoubtedly complicated, and I think is pretty well illustrated by a case under my care at present. A gentleman accidentally struck the end of his finger against some substance which hurt it rather severely at the time. In a little while it seemed better, but after three or four days it had not got well, and he came to me with a very painful terminal joint of his little finger, swollen, reddened, skin shiny over it, intensely sensitive, aching when it was not being manipulated. I followed the routine treatment, put it on a splint, and he came back to me in three or four days, and it was about the same. Then he had hot water applications and some massage, and again he came and it was just about the same. Then the inflammation had extended backwards on the finger until the next joint became swollen, and at the end of three weeks the whole little finger was uniformly swollen and sausagelike in shape and shiny. It is now about four weeks since the injury and he has acquired the habit of holding his little finger off, can't close the hand. The final joints of nearly all the fingers are mostly immovable. If I undertake to shut in all the other fingers which have not been hurt, he complains of it. I think there is no doubt that this extension of the stiffness and pain is a nervous condition resulting from the more or less constant attention to his finger muscles and arm muscles, and attempting to hold the little finger perfectly immovable. It seems to me further fixation of the hand or finger is hopeless, and I have advised him to leave off apparatus and begin to move the finger and have massage applied once or twice a day. I think I shall try the faradic current for the relief of pain and limbering up of the joints. I very much question whether fixation at the beginning was of benefit. Probably if he had given it proper attention at first, he might not have gone through this series of discomforts. He is a nervous man.

DR. M. H. RICHARDSON: I do not think Dr. Lovett need apologize for presenting this subject. We ought to judge of a subject from the frequency of occurrence and the difficulty of treatment. I think these cases ought to be treated as if some serious disease was

possibly in progress. Take the case of the woman whom he showed to-night, I think that might have resulted in loss of the finger, especially as the lateral ligaments of the joint are already lax. I have been accustomed, in what few cases I have seen of late years, to keep the joint still, and to get passive motion as soon as possible.

DR. E. O. OTIS: I saw a case sometime ago, the result of a foot-ball accident. A student received a bad sprain of the second phalanx of the finger. When he came to me sometime after, the joint was large and almost immovable, with not very much pain. It was immobilized and the splint removed every day and hot water used. As time went on he did not seem to receive much benefit, and at this time it is still in that large, more or less immovable condition. What the result will be I do not know. It is a good suggestion of Dr. Lovett's that massage be applied.

An interesting fact in this case was that he bound this finger up tightly with the other finger, and with the two fingers extended he was not only enabled to practise foot-ball, but to play in the championship games without apparent further injury to the finger.

GALL-STONES REMOVED FROM CYSTIC DUCT. SUPPURATING VERMIFORM APPENDICES. MALIGNANT TUMOR OF OVARY.

DR. M. H. RICHARDSON showed two specimens of gall-stones removed from the cystic duct during the past week. The first is a very small one. The diagnosis was made by Drs. F. C. Shattuck and Cutler, and an operation for relief was advised. The gall-stone was impacted where these gentlemen said it was, in the cystic duct of a very much contracted gall-bladder. This is the third operation on the gall-bladder I have performed for gall-stones. The gall-bladder was greatly contracted, thickened and very friable. This last condition, friability, makes all manipulations very difficult, especially that of approximation and suture to the abdominal wall.

The second case was of a gentleman of sixty-four, whose life for eight years had been made miserable by biliary colic. He had spent a portion of every year at Carlsbad, with temporary relief. Recently he returned from Carlsbad without the accustomed benefit, and has required frequent and daily injections of morphine to make him comfortable. The diagnosis of gall-stones was made long ago by his physician, Dr. J. P. Oliver, and confirmed by Dr. Fitz. We found eight large faceted stones in a row extending from the gall-bladder into the cystic duct.

Both these cases have done remarkably well. The boy now, at the end of a week, is in a very good condition. The second operation was performed two days ago, and the temperature is now normal.³

I would like to mention in this connection a case I had a year ago. It was that of a woman who had suffered many years with symptoms of biliary colic accompanied by jaundice and profound cholemia. I found the gall-bladder contracted and friable with a large gall-stone in the cystic and another in the hepatic duct. In this case, after the removal of the stones, I was confronted with the formidable condition of a large opening near the foramen of Winslow, with vast quantities of bile escaping into the abdominal cavity. I contrived to fasten a glass tube into the ragged remains of the cystic duct by which, with the

² See page 54 of the Journal.

³ Both cases made speedy recoveries. December 24, 1891.

aid of gauze packing, perfect drainage was established. The woman did well for six or seven weeks, although there was no diminution in the amount of bile discharged through the tube or of the jaundice. At the end of that time she had a gradually rising septic temperature and died from the effect of a sponge which had been left at the time of the operation in the abdominal cavity, in spite of the usual precautions taken to prevent this accident, namely, the counting of all the sponges by a special nurse, both before, during and after the operation.

I have two specimens of vermiciform appendix in both of which there has been perforation and local peritonitis. In both drainage was established among healthy intestines. In each case, as in the first cholecystotomy, I used wick drainage of iodoform gauze, in one combined with a tube. This method provides the most satisfactory drainage in septic cases in my experience. Both cases are doing very well indeed.⁴

The next specimen is one of abdominal tumor removed to-day. It was poor judgment on my part to have attempted its removal. Having started in this attempt, however, there was no possibility of abandoning the operation. It was a rapidly-growing tumor of the abdomen in a woman between fifty and sixty years of age. I had been studying the case for a week, and had come to the conclusion that it was probably malignant tumor of the ovary. I thought so, among other reasons, because of its rapid growth and the coexistence of ascites. I made an incision to-day and finding no apparent malignancy about it, as it presented, determined to remove it. On separating its adhesions to the transverse colon, I met with quite evident malignancy which I had not been able to discover before. It was then too late to retreat, the semi-solid mass having gone to pieces in careful efforts at separation. The descending colon, just below the splenic flexure, was so intimately adherent to the tumor that it was impossible to separate them. I removed a piece about four inches in length at the junction of the sigmoid flexure and the descending colon. It was very difficult, indeed, to bring the divided ends together. The arrangement of the descending colon and sigmoid flexure was a little unusual, the beginning of the sigmoid flexure being rather higher up than normal. It was not as much covered by peritoneum as in the majority of cases. Through the entire bend the disease had established itself. The divided end of the descending colon was immovably fixed in its normal position, but the other end, in the sigmoid flexure, was freely movable. It was necessary, therefore, to bring the movable sigmoid flexure up into the left flank at the posterior wall of the abdominal cavity, and to fix it by means of the ordinary Lambert stitch in this position. I was able to make a very satisfactory joint in the ordinary method. There being no peritoneal covering to the posterior portion of the cut ends I was fearful of an extravasation of feces. I therefore packed above, below and around the joint with iodoform gauze, and I think, if she survive the shock necessarily great, she will do well. Should the stitches give way, drainage will have become established and we shall have nothing more than a fecal fistula as after removal of the appendix, which will take care of itself.⁵

⁴ Both recovered well. December 24, 1891.

⁵ Died a few days later.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JANUARY 21, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

HENRY INGERSOLL BOWDITCH, M.D.

DR. HENRY INGERSOLL BOWDITCH died January 14th in the eighty-fourth year of his age, after a long illness, which he bore with such courage and cheerfulness, and manly patience, that it was a benediction to be near him.

Dr. Bowditch inherited from his father, Nathaniel Bowditch, the eminent mathematician, and his mother, Mary Ingersoll, those sterling qualities which, developed by their example and teaching, made him, in later years, a leader among men. His child-life was fortunate in the companionship of three brothers and two sisters, all very like him in having individuality and force of character. As a school-boy he was kind, generous, sympathetic, truthful, manly, but thoroughly a boy, and the shout that there was "a nigger on the common" or a fight going on between the boys of the opposing sections of the town, brought him quickly to the front. From the open-air life insisted upon by his father came the healthy mind in the sound body. The simple living, the early love of nature, the habits of industry and self-denial so common to the New England life of his time encouraged a thoughtfulness, self-reliance, independence of mind and vigor of action which have become more rare with the increase of wealth and luxury.

In college, he was the same warm-hearted, good fellow, straightforward, impulsive, pugnacious, ardent — although not an ardent scholar — sensitive and popular, always to be depended upon.

After taking the degree of A.B. at Harvard in 1828, and later the A.M., he graduated at the medical school in 1832, having also been house-officer at the Massachusetts General Hospital. Dr. Bowditch spent two years in Europe studying for the most part with Andral, Chomel and especially Louis, whom he fondly called his master. It was still the day of dogmatism and pedantry and system-making, but Louis, one of the first of the iconoclasts, was teaching the close study of nature and the careful observation, faithful records and accurate analysis of facts as the true basis of med-

ical knowledge and practice. Dr. Bowditch came back to Boston full of enthusiasm for Louis's methods, where, indeed, he found Dr. Jacob Bigelow, his senior by twenty-one years, already a pioneer in the new field. While waiting for practice he devoted much time to benevolent work and took great pleasure in helping those who needed encouragement or assistance, especially the young — interests which he kept up to the last. Having by chance been an eye-witness of the famous Garrison mob in 1835, his quick sympathy and intelligent foresight led him to devote his "whole heart to the abolition of slavery." "But," he adds in his diary, "even anti-slavery never has taken me away from constant labor for the elevation of medicine." When he became an abolitionist, church, State, the constitution and laws of the country, old friendships, social ties were all against him. He was mocked, sneered at, passed on the street without recognition by his father's old friends; but his courage never faltered, his faith in humanity and the final triumph of his cause never failed. Without even any feeling of bitterness for his opponents, he worked steadily on, with pistol in one hand carrying the runaway slave in his chaise to a place of safety; a member of the vigilance committee in 1846 and in 1850; working for the fugitive slave Latimer until his release was secured; a co-worker with Phillips and Garrison until the emancipation proclamation. When an escaped slave, Anthony Burns, was given up to his master (May, 1854), and taken in fetters down Court and State Streets with "an overwhelming force of soldiers," Dr. Bowditch dashed past the police on guard, through the cordon line, at the head of a procession of excited citizens, down to the wharf, where a devoted band of abolitionists stood in horror to see the United States cutter, bearing the returned slave, steam away. Vowing that that disgrace should never again happen to the soil of Massachusetts, they formed the anti-man-hunting league, at the instigation of Dr. Bowditch, who was its secretary. Less than a decade later he saw Colonel Shaw march down the same street at the head of his negro regiment; he lived to see slavery abolished, peace and industry established in the South, and himself honored with Phillips and Garrison, and loved by his Southern associates.

With the same qualities he conquered success in his chosen profession. He became admitting physician, 1838 to 1845, and later, visiting physician, 1846 to 1864, at the Massachusetts General Hospital, visiting physician at the Boston City Hospital, 1868 to 1871, consulting physician to the Massachusetts General, City, Carney and New England hospitals, professor of Clinical Medicine in the Harvard Medical School, 1859 to 1867, a member of the leading medical societies in Boston, president of the American Medical Association in 1876. He was a member of the American Academy of Arts and Sciences, of the Paris Obstetrical Society, of the Paris Society of Public Hygiene; and honorary member of the New York Academy of Medicine, of the Philadelphia College of Physicians,

and of the New York, Rhode Island and Connecticut State Medical Societies.

When he was appointed admitting physician, negroes were not received as patients in the hospital. He offered a test case of pneumonia, resigned his position when his negro patient was not admitted, and carried his point, his resignation not being accepted.

After he became of the first eminence in his branch of the medical profession, and his reputation had extended throughout this country and Europe, he was still the man before the physician, and kept in close touch, through the Thursday Club and constant attendance on scientific and medical society meetings, with the spirit of progress in all branches of knowledge. Whatever interested humanity interested him. He gave his assistance freely to all movements to elevate mankind, regardless of race or creed. When his fame was at its zenith, probably even his own family did not learn when his quick eye of sympathy had seen so many ways to help that after a long day's work he had given away far more than the amount of his fees, so little did his right hand know what his left hand was doing. He gave himself freely and gladly with his gift.

To his professional associates he was an inspiration; to the younger men his unfailing kindness of heart and generosity gave strength and courage; the example of his life raised them to a higher plane of living. To one who had sought advice from many older physicians, and had heard how to get practice and fame and wealth, Dr. Bowditch's words were: "Never do anything which will make you think afterwards that you have been a sneak." Even before the surgeons, in 1850, he successfully operated for empyema; to one surgeon whom he considered one of the boldest, but not willing to open a perinephritic abscess, he proposed himself to push in the scalpel where the surgeon pointed out the proper spot. In sanitary science, too, he led the way. With the eloquence of sincerity, showing to a committee of the legislature his chart indicating the prevalence of pulmonary consumption in Massachusetts, he explained to them the law which he discovered, in 1862, of its relation to soil-moisture, and did much to persuade them to create the first State Board of Health in this country, an example which thirty States have followed. When the board was appointed, in 1869, Dr. Bowditch was easily first in the estimation of the medical profession and the community for the arduous and responsible duties of its president, a position which he retained, at great sacrifice of his time and professional income, until 1879. When the powerful interests attacked by the board in the cause of the public health resisted, and the politicians threatened, and other members of the board hesitated, he pushed on, ardent and impulsive until the point was gained. If his enthusiasm carried him too fast or too far, he was always ready to modify his course. If in his vehement indignation and scathing rebuke of anything which he considered mean or unworthy he had seemed to wrong any one, he was quick with generous redress. His simplicity and earnestness were so trans-

parent that, as one of the members of the board said, there could be no real dissension in a board of which he was the chairman; and his sense of humor, love of fun, and quick intuition helped him out of many difficult places.

When the yellow fever epidemic of 1878 aroused the nation to the need of a National Board of Health, the chairmanship seemed the opportunity of Dr. Bowditch's life. No one else had the personal qualities and the reputation to fill the place. Unfortunately, the state of his health prevented his accepting it, or, indeed, of serving as a member of the board for more than a year; and there followed its melancholy wreck, which so many thought that he, if he had been chairman, might have averted.

He was one of the earliest advocates of specialties in medicine in this country, freely asking the advice of men much younger than himself, and treating with respect the sincere opinions of the least experienced if given, as he gave his opinions, without assumption. He was one of the first to believe in women as physicians, and thought it but justice to them, as well as good policy for the community, to give to them the same advantages of study as to men.

More than 90,000 manuscript pages of records of cases of private patients, ten printed papers and sixty-six pamphlets printed in twenty-nine journals or society transactions, with numberless short articles on various subjects, attest the industry of his life. His letters and notes and diaries are full of his work with scarcely a mention of his honors.

His epoch-making work in medicine was his thoracensis, his first operation with the Wyman aspirator having been done in 1850, some time after Dr. Morrill Wyman's "brilliant operation." But his greatest title to honor from his professional associates was his character. An earnest searcher after truth, he stimulated and encouraged good work in others. Honest, fearless, outspoken, he made friends of his enemies by the simplicity, purity, sincerity, and unselfishness of his purpose. He compelled an admiration of the right and a hatred of wrong.

At the meetings of the American Medical Association, at which he was constant in attendance so long as his health permitted, men from Maine to California caught the spirit of his enthusiasm, they felt the stimulus of his eager search for the truth, they were so filled with admiration of his noble life that they went back to their work with a higher sense of personal duty and professional obligation.

During our civil war Dr. Bowditch was an untiring worker in numberless ways. He was enrolling-surgeon, and to him more than to any other single individual was due the persistent effort by which Congress passed the law creating an efficient ambulance service in the army. The ardor of the patriot accepted the loss of the son bearing his grandfather's name, killed while leading a squadron of cavalry at Kelly's Ford; but to the father's love it was a life-long grief, how deep few only could know.

Dr. Bowditch's home-life was ideal, "I think of his home as more filled with love than any other home I ever knew," writes one of his friends. In one respect Dr. Bowditch possessed a remarkably judicial mind: in that he clearly recognized his own defects. Indeed, he was not only always modest and free from assumption, but he was his own severest critic even where others saw only cause for praise. When he erred in judgment, he did so from spontaneous self-forgetfulness born of a righteous impulse. In the days of chivalry he would have been the knight without fear and without reproach.

Some of his more important medical publications are:

- The young stethoscopist; or, the student's aid to auscultation. 1848.
- On pleuritic effusions, and the necessity of paracentesis for their removal. 1851.
- On paracentesis thoracis, with ~~an~~ analysis of cases. 1852.
- On paracentesis thoracis. An analysis of twenty-five cases of pleuritic effusion in which this operation was performed. 1853.
- On paracentesis thoracis. 1857.
- Paracentesis thoracis: a *résumé* of twelve years' experience. 1863.
- Thoracentesis, and its general results during twenty years of professional life. 1870.
- Two fatal cases of pleuritic effusion. Would not thoracentesis have saved life? European and American treatment of pleurisy. 1882.
- Topographical distribution and local origin of consumption in Massachusetts. 1862.
- Consumption in New England; or, locality one of its chief causes. 1862.
- Is consumption ever contagious, or communicated by one person to another in any manner? 1864.
- Consumption in New England and elsewhere; or, soil-moisture one of its chief causes. 1868.
- Consumption in America. 1869.
- Open-air travel as a cure and preventer of consumption, as seen in the history of a New England family. 1889.
- Report of the committee on climatology and epidemics in Massachusetts, 1868-69. 1869.
- Preventive medicine and the physician of the future. 1874.
- Annual address in state medicine and public hygiene. 1875.
- Address on hygiene and preventive medicine. 1876.
- Public hygiene in America. 1876.
- Sanitary organization of nations. 1880.
- Yellow fever epidemic: what should be done? Imperative need of a national sanitary board. 1888.
- An apology for the medical profession as a means of developing the whole nature of man. 1863.
- Letter from the Chairman of the State Board of Health concerning houses for the people, convalescent homes, and the sewage question. 1870.
- The medical education of women. The present hostile position of Harvard University and of the Massachusetts Medical Society. What remedies therefor can be suggested? 1881.
- Intemperance in New England. How shall we treat it? 1872.
- Intemperance, as governed by cosmic and social law. How can we become a temperate people? 1872.
- Inebriate asylums, or hospitals. 1875.
- Abuse of army ambulances. 1862.
- A brief plea for an ambulance system for the army of the United States. 1863.
- The past, present, and future treatment of homœopathy, eclecticism and kindred delusions which may hereafter arise in the medical profession, as viewed from the stand-

points of the history of medicine and of personal experience. 1887.

Louis (P. C. A.). Pathological researches on phthisis. Translated from the French, with introduction, notes, additions and an essay on treatment. By Ch. Cowan. Revised and altered by H. I. Bowditch. 1836.

Louis (P. C. A.). Memoirs on the proper method of examining a patient and arriving at facts of a general nature. From the French, by H. I. Bowditch. 1838. Brief memoir of Louis and some of his contemporaries in the Parisian school of medicine of forty years ago. 1872.

THE TREATMENT OF INFLUENZA.

In the prophylaxis of influenza it must be remembered that the disease is a something (germ or other morbid factor) plus, not infrequently, a severe cold. A catarrh or cold is a mechanical congestion of the naso-pharyngeal mucous membrane due to exposure to alternating temperatures, not necessarily accompanied by fever or any constitutional disturbance. This congested mucous surface furnishes a favorable nidus for the influenza germ as well as for the germs of ordinary suppuration. The germs or their protamines find entrance into the blood and produce the rigors and other constitutional symptoms. The main prophylactic indication, then, would be to avoid, as far as possible, the causes of ordinary colds. When once the congestion is established, means should be taken to prevent this extending, and to destroy any germs that have effected lodgment on the congested membrane. Here the use of diaphoretics (a warm bath, a vapor bath, heaters, liquor ammoniac acetatis, jaborandi, Dover's powder—the patient being in bed), may be salutary; the symptoms of prostration are to be treated by abundant stimulants. The menthol spray, or eucalyptus inhalations, stimulate the local circulation, and are perhaps germicides. The eucalyptus may be inhaled from a handkerchief, and a two to five per cent. of menthol in some form of liquid vaseline be injected into the nostrils in chronic catarrh.

There is no special treatment for the bronchitis of influenza. The acuteness of the attack, the oppression, the teasing, dry cough, the scanty expectoration of the first stage, indicate the need of expectorants and sialogines, whilst the prostration indicates the disadvantage of their administration. Ten drops of wine of ipecac, one drop of tincture of aconite, five grains of nitrate of potash in a dessert spoonful of liquor ammoniac acetatis, constitute a convenient mixture for this stage of the disease; the dose may be given every two hours during both day and night, or the tincture of lobelia inflata in five-minim doses may be substituted for the ipecacuanha wine. Citrate of potash in thirty-grain doses with lemon juice and syrup is a favorite combination, making a mixture which is very pleasant to take. No one will question the beneficial effects of hot fomentations and cataplasmas to the chest, especially when there is pain and dyspnoea. The old custom of giving an emetic at the onset of a severe bronchial attack has gone out of fashion, still there are times when nothing will so speedily relax the tightened

bronchi, allay the element of spasm and promote expectoration, as a full dose of ipecac or turpeth mineral. The latter emetic is especially applicable to children with abundance of sub-crepitant rales all over the chest, dyspnoea, and other symptoms of capillary bronchitis.

When expectoration has begun, and in influenza it sometimes does not begin at all, there is probably no better expectorant than carbonate or muriate of ammonia. The latter, if rubbed up with extract of licorice and taken in emulsion, in water or in syrup, is not especially disagreeable to the taste. The aromatic spirits of ammonia may be given in syrup of tolu or syrup of senega, and often no other expectorant will be needed. Marotte has recently published a paper in which he recommends, in order to oppose the pulmonary manifestations of *la grippe*, the employment of chloride of ammonium in doses amounting to two or three grammes daily. He would give the salt in capsules or cachets, the dose being fifty centigrammes.¹

As the adynamic symptoms are always marked, a supporting treatment should be instituted from the first, and alcoholic stimulants are frequently indicated. A tablespoonful of whiskey in a glass of milk is a favorite combination with many. Or the milk is given in teacups every two hours, and is alternated with a glass of grog or champagne. The alcohol often seems materially to aid expectoration besides combating restlessness and insomnia. It is especially in broncho-pulmonary cases complicated with weak heart and pulse that alcohol is a necessity. Physicians doubtless do not sufficiently utilize the stimulating and supporting effects of strong coffee, which may often be allowed to advantage in influenza *ad libitum*.

Where the cardiac enfeeblement is very marked, there can be no question as to the benefits of digitalis, strophanthus, caffeine, and sometimes of nitro-glycerine. In the pneumonia and broncho-pneumonia of influenza, the leading indication is often to support the struggling heart, and digitalis may be given here with often happy effects. An eligible form is the infusion, of which a teaspoonful may be given every two hours for a day or two, then strophanthus or caffeine may be substituted for the digitalis.

Many practitioners have great faith in sulphate of quinine, both as an abortive means in the early stages (abridging duration of the attack), and as a supporting agent all through the sickness. By general consent, however, quinine has of late been relegated to a secondary and subordinate place in the therapeutics of this and other affections, being given in rather small doses and for its tonic effect.

For the nervous symptoms of influenza, — the headache, the backache, the pains in the limbs, the restlessness and insomnia, etc., there seems to be nothing so good as acetanilid or phenacetin, and no medicines are more generally prescribed. Just how these medicines act is not yet known, but they certainly have a marked action in allaying the rheumatoid and neuralgic pains

¹ Bull. et Mem. de l'Académie de Médecine, June 16, 1891.

of influenza, and, they also combat the fever-element and relieve the insomnia. A recent writer in the *Lancet* even affirms that acetanilid is curative of the bronchitis, destroying the micro organisms that pervade the mucous membrane and the sputum; and that he has found it to cause the cough to disappear. Other practitioners may not have seen the same results, but there is abundant testimony that phenacetin or acetanilid are invaluable and safe medicaments in influenza. The former may be given in ten and the latter in five grain doses every two hours until the muscular or neuralgic pains cease; two or three doses generally prove sufficient. Some prefer to give stimulant with these drugs, as it hastens their action and counteracts any depressing effects. When the muscular pains are obstinate, salol, five grains, or salicylate of soda, fifteen grains, have been recommended.

A capital point in the treatment is to watch the patient, that he be not allowed to go out too soon, for cases are not rare where, after a light attack, exposure to cold has been followed by fatal pneumonia.

We can but just allude to Maclagan's treatment of influenza by salicine in large doses. This writer reports a series of cases which, he claims, go to show that salicine in doses of twenty grains every hour for five or six hours, then every two hours for a day "arrests the course of the disease as effectually as it does that of acute rheumatism when given in the same manner." In all his reported cases the cure was rapid, "the temperature falling to the normal, and convalescence commencing in all within twenty-four and in most within twelve hours of the commencement of the treatment."

BOMB-THROWING AND RESPONSIBILITY.

AT a meeting of the New York Society of Medical Jurisprudence and State Medicine, held January 10th, Dr. N. E. Brill, the President-elect, delivered his inaugural address, taking as a subject: "Some Medicolegal Reflections on Bomb-Throwing and Responsibility." As a safeguard against bomb-throwing and dynamite terrors, Dr. Brill advised a more stringent regulation of the manufacture and sale of explosives, and a restriction of the dissemination of pamphlets instructing the public how to make explosives. In the course of his remarks he urged the abolition of the "Anti-Kidnapping Society," through whose efforts he believed that a number of insane persons had been set at large. The title of this society, he said, was an insult to the medical profession, its members claiming that physicians were corrupt and open to bribes, and that they had sent patients to the insane asylum who were not lunatics. Such a society might, perhaps, have been a desirable organization in the Dark Ages, but its existence in the 19th century was an insult to the people and to the Government. He recommended that the form of committing the insane by magistrates to County or State asylums be taken away, and that all the insane arrested for a felony should be indicted by a

grand and go through the usual course of trial before a petit jury. If, at this trial, it should be proved that they were insane, they should be sent to the State Asylum for Insane Criminals. In the direction of reform he also recommended the transferring of the county asylums of New York and Kings Counties to the control of the State. It is doubtless true that for every sane man whose freedom is improperly or injudiciously interfered with, many lunatics are allowed to remain abroad who should be under restraint.

Incidentally Dr. Brill defended the electrical execution law, considering this the most humane method of execution yet devised. His conclusions, he said, were based upon his personal critical supervision of the recent execution of the murderer Loppy at Sing Sing prison, at which he acted as the representative of the Society of Medical Jurisprudence. It was his belief that the death was instantaneous and practically without any painful sensation to the criminal. The electric chair, however, was not yet perfect, and he advised that a special dynamo should be constructed for the infliction of the death penalty with a power of 2,500 volts.

MEDICAL NOTES.

PRIZE FOR AN ESSAY ON TUBERCULOSIS. — The Paris Société de Médecine offers a prize of 1,500 francs together with a gold medal, to the author of the best essay on tuberculosis before the end of 1892.

THE CREW OF THE BALTIMORE. — At the recent investigation of the attack on the *Baltimore's* crew in Chili, the naval surgeons testified that two of the sailors were killed, five seriously wounded and twelve received slighter wounds. The death of Turnbull was caused by neglect and bad treatment in the hospital where he was carried by the police. His death was due to septicaemia.

SUICIDE AMONG PHYSICIANS. — The Chicago *Tribune* notes as an interesting fact, not only that physicians headed the list of suicides last year, but that they have headed it every year in the last ten. This promises to be still more conspicuous this year, as in the first twelve days of the present month no less than seven physicians have committed suicide in the United States.

FAILURE OF AN OSTRICH'S DIGESTION. — The death of a well-known ostrich belonging to a circus is reported from Cincinnati as having been due to influenza. At the post-mortem a diamond pin, of the value of \$800, was found pinned in his stomach. The pin had been picked last summer from a gentleman's shirt front in Montreal.

HORSE-FLESH FOR FOOD. — The United States Bureau of Animal Industry has discovered that horse-flesh in large quantity is being shipped to Europe from a place on Long Island, N. Y. Some of it is supposed to pass there as beef, and part of it is used for making sausages, which are then sent back to this country.

NEW HEALTH DEPARTMENT IN LONDON.—The act of Parliament establishing a public health department for the city of London went into force the first of the year. This is the first time that a city has had a department attending solely to matters of health.

POST-MORTEM CONVICTION.—According to the *Medical Press*, a French soldier, finding himself accused of having stolen some gold coins, swallowed them. He escaped conviction, but shortly afterwards became sick and died from acute indigestion. At the autopsy, twenty-one coins were found in his stomach.

THE SPREAD OF SMALL-POX IN CANADA.—Surgeon Spencer C. Devan, of the Marine-Hospital Service, having been sent to Canada to investigate the recent epidemic of small-pox, has submitted a very interesting account of his investigation to the Marine Hospital Bureau. The disease is believed to have been brought into Quebec by the steamship *Brazillian*, last June. On her way to Montreal she stopped at Quebec for four hours. She had had several cases of small-pox on her voyage from London. On the 1st of August, a patient who had been in the hospital in Quebec for more than eight months was found to have small-pox, probably brought to the hospital from the steamer by a seaman. Both of the nurses who had attended this seaman contracted small-pox, one of them was taken to her home and gave the disease to a nurse-girl named Bujold. The girl, as soon as the eruption appeared, started for her home in Carleton. In order to get there she had to go by rail for some distance and the remaining part of her journey by steamboat. A large part of the small-pox epidemic appears to be directly due to this journey. Being alone and sick, a number of persons both on the train and the steamboat offered her assistance and from her contracted small-pox which was carried into their native towns. One family returning, after an absence of two years, sat with this girl in the train for some time. When they arrived at their destination, they were given a reception by their friends and relations, and succeeded in spreading the disease pretty thoroughly in that town. Investigating the different outbreaks, a direct clue was found in several instances showing that the infection came originally from the girl Bujold.

NEW ENGLAND.

MORTALITY OF BOSTON FOR THE WEEK.—During the past week fourteen deaths were recorded as being due to influenza alone, and thirty as indirectly due to it. The total number of deaths was 286, making the death-rate for the week 32.3. Of this number deaths due to diphtheria were 9, scarlatina 5, consumption 26, pneumonia 74, heart disease 21, and bronchitis 31. The number of persons who died over sixty years of age was 92.

BOSTON NURSES' CLUB.—A Nurses' Club has been recently organized in connection with the Training-school for Nurses at the Boston City Hospital. At the meeting for organization, Dr. G. H. M. Rowe,

Superintendent of the Hospital, stated that the aim of the club is to give a wider intelligence in the practice and ethics of nursing; a better knowledge of the three departments of hospital, private and district nursing; the stimulus that results from interchange of opinion and experience; the promotion of social acquaintance and an *esprit de corps* between the past and the present members of the school.

RECENT APPOINTMENTS.—At the last meeting of the Board of Overseers of Harvard College the following appointments were confirmed: George Wells Fitz, M.D., instructor in physiology and hygiene for 1892-93. Henry Fiske Leonard, M.D., M.D.V., instructor in anatomy in the Veterinary School for the remainder of the year 1891-92. Kenelm Winslow, M.D.V., M.D., assistant professor of veterinary therapeutics for five years from September 1, 1892.

HOTEL-KEEPERS MUST SELL PURE MILK.—By a recent decision of the Supreme Court of Massachusetts, the selling of impure milk by hotel-keepers is punishable under the same statute which applies to milk dealers in general.

NEW YORK.

THE NEW YORK TRAINING-SCHOOL FOR NURSES.—The nineteenth commencement of the New York Training-school for Nurses attached to Bellevue Hospital was held on January 12th, when a class of thirty was graduated. The report of the Secretary gave the annual statistics of the institution, and stated that during the year the Edith Sumner Home for the relief of the hard-working nurses had been opened, and also that four rooms had been built over the Marquand pavilion, at Bellevue, for the special use of nurses who were taken ill while on duty. The address to the graduates was delivered by Dr. Frederic S. Dennis.

MORTALITY FOR THE WEEK.—During the week ending January 9th, the total number of deaths reported in the city was 972, and the number of deaths from influenza and complications, 89. This is the largest mortality reached during the present rather mild epidemic, and since then there has been a considerable reduction in the number of deaths.

THE ADIRONDACK PARK.—The annual report of the State Board Commissioners just presented to the Legislature, shows that there has been an increase of about 15,000 acres in the extent of the Adirondack preserves during the year, partly under the provisions of the act of 1890, appropriating \$25,000 for the purchase of land at not more than \$1.50 per acre. If a further appropriation is made about 50,000 acres additional can at once be purchased at the same rate. The report speaks at length of the legislation necessary for the proposed establishment of a State Adirondack Park, and states that there is a universal demand for this park by the press and people of the State. The original idea called for forest preservation, with reference only to protecting the head-waters of the rivers, and to providing a future economical and perpetual timber supply; but lately the acquisition of

this territory has been urgently demanded by the medical profession and the public for the purposes of a health and pleasure resort.

THE STATE BOARD OF MEDICAL EXAMINERS met at Albany on January 15th, and seventeen out of the twenty-one members composing it were present. Since the new medical law went into effect, September 1st, 1891, nineteen persons have applied for licenses to practice medicine in the State, two-thirds of whom were graduates of foreign universities. Eight persons have presented themselves for examination, and of these seven passed. The second examination of candidates for license to practice will be held in the cities of New York, Albany, Syracuse and Buffalo, on January 26, 27, 28 and 29.

INSANITY IN THE STATE.—The annual report of the State Commissioners in Lunacy, which is now in course of preparation, shows that during the year ending October 1, 1891, 827 insane patients were transferred from county institutions to the State hospitals. This leaves 1,215 insane still in the county institutions of those counties not exempt from the provisions of the State Care Act; but within a few months it is expected that they will all be transferred to the State hospitals, as the construction of the necessary new buildings at the different hospitals will have been completed by the 1st of October, 1892. During the year there was an increase of 345 in the total number of insane patients.

Miscellany.

MENTAL SYMPTOMS AFTER SURGICAL OPERATIONS.

KIERNAN cites a formidable list of authorities from Ambrose Paré to Horatio Wood, showing a profound nervous effect produced by operation.¹ He has found 186 cases of profound mental change following operation; 35 cases after operation for cataract; 65 following gynecological operations, and the remainder resulting from plastic operations, amputations, manipulations, etc. In 15 cases there was larvated epilepsy precedent to the operation; in 10 hysteria major was present; in 30 cases a neurotic element existed; in 35 cases the patients have arrived at periods of involution when instability of the nervous system usually results. In 10 cases only was the influence of blood-poisoning demonstrated.

The acute types of mental affection following operation are aptly designated as "acute confusional insanity." In the larvated epileptic cases, the neurotic, and the hysterical, the prognosis is good. In some of the cases occurring at periods of involution senile degenerations are precipitated. The majority of blood-poisoning cases died. Typho-mania is sometimes observed.

The moral treatment of the patient precedent to the operation is the best prophylaxis. If to the dread of the operation be added dread of the operator the nervous perturbation will necessarily be far greater. Sedatives and other measures tending to calm agitation are ne-

necessary. Quinine is strongly indicated. Opium and not chloral hydrate or the bromides will, as a rule, be found a most valuable aid in most of the cases. In many of the hysterical cases salix nigra and monobromate of camphor give good results.

INFANTILE ATAVISM.

DR. LOUIS ROBINSON,² taking advantage of the material furnished by the maternity ward of an English work-house, has studied certain peculiarities of newborn babies, which he thinks may, by the theory of evolution, throw light upon the origin of the human race. As the young of certain anthropoids are obliged to cling to their mothers or to trees, he tested the clinging power of young infants, and found that they all had a very durable grasping power, and that the strongest were able to hang by their hands and support their whole weight for over two minutes and a half. The author considers that the amount of strength in the flexors of the hand and fingers in newly-born children is best explained by its being a survival from the tree-climbing period of man's history. The effort made by infants to curl their toes over anything, he ascribes to the same origin. Another point is the flexed state of the thighs. Other animals, although twisted and cramped in the egg or the uterus, adopt the position of adults as soon as they are born, whereas the thighs of young infants seem to assume the position existing in apes.

As a criticism of the theory that the disproportionate size of the anterior half of the body of the human fetus is due to better nourishment by the fetal circulation, he calls attention to the large hind quarters of new-born quadrupeds. A suggestion is made that the axillary and pubic hair in the adult human being, may be partly accounted for as the remnants of handles, to which our four-handed ancestors clung in their infancy.

THE MEDICAL DEPARTMENT OF THE ARMY.

A CIRCULAR of information has been issued by the Surgeon-General for medical men who may be desirous of entering the United States Army Medical Department.

The medical department of the army consists of one surgeon-general with the rank of brigadier-general; one assistant surgeon-general, one chief medical purveyor and four surgeons with the rank of colonel; two assistant medical purveyors and eight surgeons with the rank of lieutenant-colonel; fifty surgeons with the rank of major; and one hundred and twenty-five assistant surgeons with the rank of first lieutenant of cavalry for the first five years of service, and of captain of cavalry subsequently until their promotion by seniority to a majority.

With the rank stated in each case the pay and emoluments of the rank are associated. For the first five years the medical officer receives \$1,600 per year. He then receives \$2,200 a year, which increases with length of service and promotion.³ Compulsory retirement at the age of sixty-four years increases the rapidity of promotion to the younger men; and when retirement is effected either by age, or by the accidents

¹ American Journal of Medical Sciences, December.

² British Medical Journal, December 5, 1891.

of service prior to reaching the retiring age, the rate of pay subsequently drawn is seventy-five per cent. of the total salary and increases of the rank held by the individual at the time of his retirement. The medical officer has the right of selecting quarters in accordance with his rank. The authorized leave of absence amounts to thirty days annually. This leave is not forfeited if not taken during the year.

A commission in the Medical Department of the Army is an instrument which is good for life, premising conduct consistent with its retention on the part of its possessor; but it involves no contract which binds the individual to service for any given number of years.

A young medical officer on appointment is usually assigned to duty for a few months at some large post. After this he goes to some post west of the Mississippi river, where he serves a tour of duty of four years. An assignment in the east follows the leave of absence which is usually taken at this time; and in after years his stations are selected so as to give him a fair share of service at what may be called desirable posts as an offset to the time spent at less desirable stations.

Instructions for candidates for the service will be found on page 720 of the JOURNAL of December 31st.

An Army Board meets every few months for the examination of candidates, who must be between twenty-one and twenty-eight years of age (without any exceptions), and graduates of a regular medical college, evidence of which, the diploma, must be submitted to the Board. The physical examination is rigid; and each candidate is required to certify "that he labors under no mental or physical infirmity, nor disability of any kind, which can in any way interfere with the most efficient discharge of any duty which may be required." Oral and written examinations on subjects of preliminary education, general literature, and general science are required as well as on different medical subjects. Clinical examinations, medical and surgical, at a hospital, and the performance of surgical operations on the cadaver form a part of the examination. An applicant failing in one examination may be allowed a second after one year, but not a third.

DR. BUCKMINSTER BROWN.

AT a meeting of the Boston Society for Medical Improvement, held January 11, the following action was taken, on motion of Dr. Francis Minot:

In taking official notice of the death of Dr. Buckminster Brown, the Society desires to record its high estimation of his personal character and professional eminence, and its regret at the loss of one of its oldest and most respected members.

Although compelled by ill-health from his youth to lead a life of extreme care and regularity, and unable to undergo the fatigues of general practice, Dr. Brown succeeded by his industry and perseverance in attaining a large practice in orthopedic surgery, of which he became one of the most distinguished representatives, both in this country and abroad.

The Society respectfully offers its sincere sympathy to the family of Dr. Brown in the affliction which they have sustained by his loss.

Dr. E. H. Bradford being unavoidably absent, the following was read for him by Dr. E. G. Brackett:

To Dr. Buckminster Brown belongs the credit of having introduced into this country the best of the English school

of orthopedic surgery (at that time the leading and most active school), and of having placed this specialty in America on a most excellent foundation. But he was in no true sense a follower, as his mind worked independently; in many of his methods he was bolder than many of his English contemporaries; and in thoroughness and persistency he equalled and surpassed his teachers.

Conservative by nature, too scholarly and well trained to accept without cautious reserve brilliantly announced cures and speedily successful procedures in the treatment of affections essentially chronic, he relied chiefly upon the painstaking measures which aid and cure through daily attention. Although he relied chiefly upon appliances in the treatment of deformity, he had the instincts of a surgeon and believed in operative methods wherever it was proved that operation was beneficial. He, by no means belonged to the more timid school of orthopedic surgery, which shuns operation, though his experience was chiefly limited to non-operative procedures. The methods which he worked in, have, in the progress of surgery, in some instances been superseded; but his work in club-foot, in tenotomy, in infantile paralysis, in correction of right-angled contraction at the hip and knee-joint, and especially in the cure of congenital dislocation, by long-continued traction and manipulation, will always be of value in orthopedic surgery.

His tastes were essentially scientific in the best sense, and his work is characterized by a tenacity of purpose and a persistency not to be surpassed; and to whomsoever he was bound by the contract of professional duty he gave his whole attention and ability with untiring zeal, and that in spite of obstacles in the lack of physical vigor which none could appreciate who did not know him. He husbanded his resources carefully and spent them lavishly in his work.

Besides his achievements he left as a legacy to his successors an example of loyalty to purpose, unremitting persistency, and a courage always superior to the obstacles and limitations surrounding his life.

THERAPEUTIC NOTES.

WARM ETHER.—Dr. Partagás, of Barcelona, has introduced an apparatus for keeping ether at a temperature of eighty-eight degrees during its administration. He claims that anesthesia produced by warm ether is much more satisfactory and may be continued for a longer time than by the cold vapor.

TINCTURE OF IODINE.¹—A good plan to prevent the spilling of iodine solutions is to fill the bottle with absorbent cotton, pouring in the solution to complete saturation and emptying all superfluous liquid. Enough remains to saturate any brush, etc., that may be thrust into the bottle, yet the bottle may be carried about without any risk of leakage or spilling.

ANTISEPTIN.²—Radlauer considers antiseptin, introduced by him into therapeutic use as a chemical combination, and denominates it the iodo-borothymolite of zinc. But analysis of this substance by F. Goldmann shows that it is not a definite chemical compound, but only a mixture of iodide of zinc, thymol, boric acid, and sulphate of zinc. The proportions are as follows:

B Zinci sulphatis	85 parts
Zinci iodidi)	
Thymoli }	85 2/3 parts
Acidi borici	10 parts M.

METHYL BLUE FOR NEURALGIA.—Immerwahr³ has tested the action of methyl blue in different forms of neuralgia. No unpleasant effects have been observed. The substance is given in doses of from one

¹ Medical Press.

² Satellite, January.

³ Deutsche med. Woch., No. 41 1891.

and a half to three grains, three times a day. The results were good in case of trigeminal neuralgia, also in nervous headache and depression from alcohol. In two cases of herpes zoster the great pain was much relieved.

Correspondence.

THE BI-CHLORIDE OF GOLD FRAUD.

BOSTON, January 19, 1892.

MR. EDITOR:—Not far from a century ago the civilized world was ringing with the praises of "Perkinism." The story is old and oft-repeated, but will bear a brief retrospect.

Elisha Perkins, then living in Connecticut, had introduced to public notice his "tractors" or "pullers-out-of-disease," with which he cured many cases of rheumatism, gout, and disorders of the nervous system, by the application of these tractors to the body. The apparatus consisted of two pieces of metal (brass and steel) highly polished, to appear like gold and silver. They were made in a small village near New Haven at a cost of twelve and a half cents a pair, and were sold by Perkins for twenty-five dollars. Perkinism spread rapidly, and soon made its appearance in England, where a Perkinian Institute was founded, and reports of 5,000 cases were published. Certificates were obtained from the highest sources, and Perkins soon found himself the possessor of a fortune.

The Archbishop of Canterbury was implored to compose a new prayer, to be used in all the churches, that no evil powers might be allowed to impede the magic workings of the estimable gift of Perkins.

Fessenden celebrated the discovery in the following rhyme:

" See pointed metals bleed with power to appear
The ruthless rage of merciless disease;
O'er the weak part a subtle fluid pour,
Drenched with invisible galvanic power,
Till the palsied, staff and crutch forego,
And leap exulting, like the bounding roe."

The exposure of the Perkins fraud was the work of two physicians, who substituted two bits of painted wood, made to resemble the metallic tractors. With these they wrought many marvellous cures, and published a volume of reports upon them. When the true character of these substitute tractors became known, Perkinism was no more.

About twenty years ago several "opium-cures" made their appearance, some of which were also proclaimed as remedies for the alcohol habit. The proprietor of one of these nostrums was arrested for alleged complicity in the Robin Hooding cases at Somerville; another was a vendor of obscene literature in Chicago; still another was the notorious proprietor of the "Scotch Oats Essence,"—a preparation which immediately died a natural death as soon as its true character was made known.

All these articles contained opium or morphia in some form as their active ingredient, and depended for their success upon the fact that the purchasers, instead of being patients, as they innocently believed themselves to be, soon became the victims of the rascals who advertised these nostrums, and thus succeeded in getting the deluded victims into their net. It was a modern version of the old fable, "Will you come into my parlor, said the spider to the fly?"

Then came the "double chloride of gold cure," as it was at first named, as fraudulent as all the rest of the tribe, in that it contained no gold whatever. As the chemist who analyzed the samples for the State Board of Health said, "It gave no reaction for the presence of even a trace of gold therein." With this fact in view, the motive for calling it a "gold-cure" becomes sufficiently evident.

The fraudulent character of these articles was first

shown up by the Cumberland County Medical Society of Maine, and again by the Middlesex East Medical Society of Massachusetts, and still later by the State Board of Health of Massachusetts in its report for 1885, in which it was stated that twenty different "cures" for the opium and alcohol habits were examined by the chemist of the Board, and all were found to be of a fraudulent character.

The "cure" of a confirmed inebriate requires something more than drugging, either by the stomach or by hypodermic injection, or otherwise. The report of the State Board of Health, already referred to, says on this subject, "A cure must of necessity combine a treatment which deals with the entire physical and moral nature of the sufferer, and must be more thorough and far-reaching than any mere system of therapeutic drugging can possibly accomplish."

All of these parties publish long lists of endorsements from statesmen, clergymen, lawyers, physicians and business men. As a sufficient comment upon this fact, the history of all patent nostrums shows that the obtaining of endorsements is a very easy matter. As a matter of fact, there is also abundant evidence that in many cases the endorsements were fraudulently obtained.

When some bright young medical man shall stily substitute a harmless placebo, in place of the usual "bi-chloride" treatment, and "cure" his patients with the substitute as successfully as Keeley professes to have done, the bi-chloride castle of this century will tumble to the ground, like the Perkinism of 1796, and be known only as a thing of the past.

Very truly yours,

S. W. ABBOTT, M.D.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 9, 1892, TO JANUARY 15, 1892.

CAPTAIN HENRY S. KILBOURNE, assistant surgeon, U. S. A., is relieved from duty at Willet's Point, N. Y., and will report in person to the Sup't. U. S. Military Academy, West Point, N. Y., for duty at that station, relieving CAPTAIN W. FITZHUGH CARTER, assistant surgeon, U. S. A. Captain Carter, upon being relieved by Captain Kilbourne, will report in person to the commanding officer, Willet's Point, N. Y., for duty at that station.

MAJOR JULIUS PATZKE, surgeon, having been found by Army Retiring Board incapacitated for active service on account of disability incident to the service, is by direction of the President, retired from active service, to take effect January 19, 1892, under provisions of Section 1251, Revised Statutes.

Leave of absence for one month is granted CAPTAIN WALTER W. R. FISHER, assistant surgeon, U. S. A.

CAPTAIN MARSHALL W. WOOD, assistant surgeon, U. S. A., now on leave of absence, will report to the commanding officer, Fort Columbus, N. Y., for temporary duty at that post during the absence of CAPTAIN W. W. R. FISHER, assistant surgeon, U. S. Army.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 16, 1892.

J. PARKER, surgeon, ordered to the U. S. S. "Charleston." C. H. WHITE, medical inspector, detached from U. S. S. "Charleston" and ordered home.

GEORGE A. LUNG, assistant surgeon, ordered to examination for promotion.

PATRICK H. BRYANT, assistant surgeon, ordered to examination for promotion.

LUTHER L. VON WEDEKIND, assistant surgeon, ordered to examination for promotion.

THE INTERNATIONAL EXECUTIVE COMMITTEE OF THE PAN-AMERICAN MEDICAL CONGRESS.

The Committee on Organization of the Pan-American Medical Congress at its meeting at St. Louis, last October, elected the following International Executive Committee: The Argent-

ine Republic, Dr. Pedro Lagleyze, Buenos Ayres; Bolivia, Dr. Emilia Di Fonseca, La Paz; Brazil, Dr. Carlos Costa, Rio de Janeiro; British North America, Dr. James F. W. Ross, Toronto; British West Indies, Dr. James A. De Wolf, Port of Spain; Chile, Dr. Moises Amaral, Santiago; United States of Colombia, Dr. P. M. Ibañez, Bogota; Costa Rica, Dr. Daniel Núñez, San José; Ecuador, Dr. Ricardo Cucañon, Guayaquil; Guatemala, Dr. José Monteris, Guatemala Nueva; Hayti, Dr. D. Lamotte, Port au Prince; Spanish Honduras, Dr. George Bennett, Tegucigalpa; Mexico, Dr. Tomas Nunez, Ciudad de Mexico; Nicaragua, Dr. J. L. Uriarte, Grenada; Peru, Dr. J. Casamira Ulloa, Lima; Salvador, Dr. David J. Guzman, San Salvador; Spanish West Indies, Dr. Juan Santos Fernandez, Habana; United States, Dr. A. Vander Veer, Albany, N. Y.; Uruguay, Dr. Jacinto De Leon, Montevideo; Venezuela, Dr. Elias Roden-guez, Caracas.

Hawaii, Paraguay, Santa Domingo, the Danish, Dutch and French West Indies are not yet organized. Nominations of local officers have been received from a majority of all the members of the International Executive Committee and a number of the lists have been confirmed by the Committee on Organization. These will be announced as rapidly as acceptances are received.

CHARLES A. L. REED, *Secretary-General.*
Cincinnati, January 15, 1892.

SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held at M. M. May, January 25, 1892, in the Medical Library, 19 Boylston Place, at 8 o'clock p. m.

Dr. A. L. Mann, "Notes on Typhoid Fever" from 670 Cases at the Boston City Hospital in 1890 and 1891."

Dr. C. L. Sudler, "The Management of Compound Dislocations of the Ankle-Joint."

Dr. G. W. Gay will report some Cases of (Esophagotomy).
G. G. SEARS, M.D., *Secretary.*

RECENT DEATHS.

CHARLES MARTIN, M.D., Medical Director, United States Navy, died in New York, January 14th. He was appointed assistant surgeon in 1848; surgeon in 1861, and Medical Director in 1873. He was wrecked on the coast of Patagonia in 1851 and remained there some months. He was on the Camberland in 1862, when she was sunk by the Merrimac, and on the Mohican, during both attacks of Fort Fisher. He was retired in 1884.

JOHN GEORGE METCALF, M.D., M.M.S.S., died at Mendon, January 13th, aged ninety years. He graduated from Brown University in 1822. In addition to an active practice, he held several positions of trust and importance, among them being that of State Senator, in 1858 and '59.

HENRY INGERSOLL BOWDITCH, M.D., M.M.S.S., died in Boston, January 14, 1892, aged eighty-three.

BERKELEY HILL, F.R.C.S., Vice-president of the Royal College of Surgeons; Professor of Clinical Surgery at University College, died in London, January 7th.

CONGENITAL DISLOCATION OF THE HIP.¹

BY A. M. PHELPS, M.D., NEW YORK.

SOME two years ago, Dr. John Ridlon, of New York, reported a case of congenital dislocation of the hip, the head of the bone resting on the pubes. This dislocation forward and upward is unusual. However, within a year two other cases came to my clinic at the Post-Graduate Medical School and Hospital, with the same deformity.

The deformity in each case was precisely the same. They were, in fact, anterior and upward congenital dislocations of the head of the femur. The child, illustrated in this article, had always been healthy; there was no history of injury in the case; nor of any severe labor. The mother noticed that when the child began to walk, one leg was shorter than the other, and that the feet and toes were turned out. Figs. 1 and 2 are cuts made from photographs taken of the case when first seen. They show the outward rotation and shortening seen in anterior dislocation. The case was three years old when I first saw it. I applied a long traction splint, which the child wore for a year and a half, when it died from acute meningitis. A post-mortem was permitted, and I have the specimen here, which, with your permission, I will now present.

Figs. 3 and 4 are drawings of the specimen made by Dr. Macdonald, and they very correctly represent the pathological condition found.

In the first specimen the head of the bone is seen above the rim of the acetabulum, dislocated upward and forward. The capsule of the joint is cut away to give the view.

In Fig. 4 the acetabulum is seen to be angular in shape, small and undeveloped, with the remains of the ligamentum teres. This specimen is of great interest, I believe, because, so far as I know, it is the only pathological specimen of anterior congenital dislocation of the hip reported, and it will be found of great value in studying the etiology of this deformity. It will be observed that the pressure of the head of the bone has changed the form of the anterior border of the acetabulum from concave to convex.

Etiology. — It has been taught, and it is accepted by the profession generally in America and in England, that congenital dislocation of the hip is a secondary condition, depending upon the non-development of the acetabulum.

This specimen is surely a case of congenital dislocation primary, with non-development of the acetabulum from non-use.

I am not prepared to say that all cases are like this, but surely here is a case of congenital dislocation *in utero* not due to non-development of the acetabulum.

Dr. Cornigan, who, by the way, has written an excellent monograph on this subject, believed that the dislocation was a primary one, due to reflex spasm of the muscles *in utero*, caused by some central nerve lesion in early fetal life.

A glance at the anatomy of the hip-joint will show that the muscles pass diagonally across the body from the shaft of the femur to the pelvis, being in a line with the axis of the neck of the femur.

It seems to me that dislocation of this bone could not take place by the contraction of these muscles, but, on the contrary, that contraction of the glutei muscles

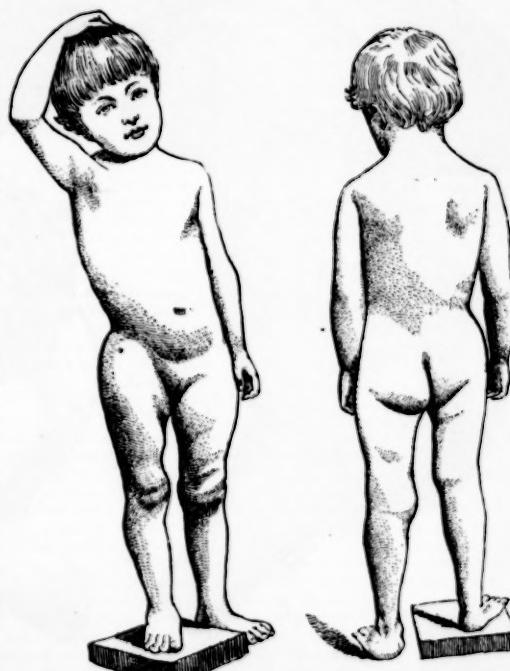

FIG. 1.

FIG. 2.

or of any of these groups, would tend to press the head of the bone more firmly into the acetabulum. A long continued spasm of muscles, sufficient to cut away the acetabulum, would destroy the head of the bone and produce a true inflammatory disease of the hip-joint.

Heredity, no doubt, has much to do with producing this deformity. Dupuytren relates the history of a case — Marguerite Cardas — who had two aunts on the maternal side, affected with lameness from their earliest attempt at walking. Marguerite's father had,

¹ Read before the American Orthopedic Association at Washington, D. C., September 23, 1891.

a sister lame from birth on the right side, who died at eighty years of age. Another sister, well formed, gave birth to a child with shortening of the right inferior extremity. This woman has a daughter by a healthy man with three inches of congenital shortening of the right leg. This girl also married a healthy man, but his father had a congenital dislocation of the right femur. She has had four children, two of whom present the hereditary infirmity.

Similar cases are numerous, and it will be difficult to doubt that hereditary predisposition exerts some in-

germ, or the operation of the formative power (by Dupuytren). This hypothesis has no support in embryogeny.

(2) Arrest of development of the cotyloid cavity. The pathological specimen here presented was certainly not produced by this cause.

(3) Certain articular maladies occurring in the fetus during intra-uterine life. No doubt diseases of the joint might occur which would produce a diastasis or even the destruction of the acetabulum, leading to a dislocation.

FIG. 3.

FIG. 4.

fluence over the recurrence of this deformity in children whose parents or ancestors have been affected by it.

Ambrose Paré, 1678, Book 16, page 347, says of hereditary causes: "Such as parents transfuse into their offspring, hence it is that crooked, not necessarily, but oftentimes, are generated by crooked, and lame by lame."

Also, "Hippocrates himself avers that infants in the very womb may have their joints dislocated by a fall, a blow, or compression."

Among the other causes enumerated, are:

(1) An original defect in the organization of the

(4) Diseases of the primitive nerve centres are said to cause a perverted condition of the excito-motor apparatus of the medulla spinalis, producing a spasm of the muscle, and resulting in dislocation. This is the favorite theory of Dr. Cornigan and M. Guerin; but I have already stated that the anatomy of the joint is such that muscular spasm, independent of other causes, could not produce dislocation of the hip. It is true that in anencephalus fetal monsters, congenital dislocation of the hip, club-foot, and other deformities are found, but there must be other pathological conditions present favoring these deformities, because many of

those monstrosities have no deformity of the extremities whatever.

It seems to me that if spasm of the muscle *in utero* produces dislocation of the hip, it ought always to produce it in the same direction, but we find that the usual form is upon the dorsal of the ilium, and this specimen which I present is one upward and forward, and Dr. Cornigan says that the dislocation may take place downward and forward, or downward and backward.

These facts, together with the peculiar anatomy of the hip-joint and the direction in which the muscles operate upon the femur, lead me to believe that this is not one of the causes *per se* of congenital dislocation of the hip.

A few years ago I saw a child one hour after it was born. The right limb was an inch shorter than the left, and there was a dislocation upon the dorsal of the ilium. I manipulated the limb in the usual method and reduced the dislocation, and the head remained in place without a retaining apparatus. This was clearly a case of dislocation which had taken place during confinement. If the deformity had not been noticed until the child began to walk, any physician would have said that this was a case of congenital dislocation of the hip.

Mr. C. B. Lockwood presented at the London Pathological Society two specimens of infants illustrating the absence of the margin of the acetabulum, with and without displacement of the head of the femur. (See *Transactions* of that Society, vol. xxxviii, page 303, 1887.)

The first case is one of microcephalic fetus, probably born at full term; a case of double-breach presentation, and after birth the thighs remained flexed upon the abdomen. The pelvis was quite well formed, with the exception of the acetabulum. The cartilaginous rim of that socket was entirely absent, otherwise the joint was normal. The capsule was capacious; the ligamentum teres longer than usual. The head of the femur was normal, lying upon a flat surface.

The second case shows absence of the margin of the acetabulum, with displacement of the head of the femur upon the dorsum of the ilium. This was a breach presentation. After birth the thighs remained flexed upon the abdomen and the legs over-extended upon the thighs. There was an ectopia of the abdomen, with considerable protrusion of the viscera, protrusion of the liver, etc.

The brain and spinal cord seemed normal. The head of the radius was displaced on to the front surface of the ulna, and the carpus toward the flexor aspect of the radius and ulna; both hips were displaced upon the dorsum of the ilium, with changes of all the structures entering into the formation of the joint. Head of the femur was irregular in shape. The cartilaginous margin of the acetabulum was absent, although the cotyloid depression seemed exceedingly deep, but not triangular. The ligamentum teres was exceedingly long, and capsular ligament capacious.

Many of the pathological specimens reported, after excisions for old dislocations, demonstrate that the acetabulum ceases to develop, and undergoes atrophic change after the head of the bone has been dislocated. It is easy to conceive of disease attacking one or both hips *in utero*, producing effusion into the joint, with or without destruction of the head; resulting, through reflex spasm of the muscle, in dislocation of the head

of the femur, which is frequently seen in hip-joint disease.

I am inclined to believe, judging from the pathological specimen here presented, and from the case of dislocation at childbirth which I saw, together with pathological specimens reported by Mr. Adams, which I have personally examined in a Pathological Museum in London, that the deformity is more frequently produced by violence of some description, or by pathological changes, the result of inflammation, than from any other cause.

We are all familiar with the "loose joints" in certain individuals who are capable of producing dislocation of almost every joint in the body. I now have a patient who can easily dislocate the right hip and reduce the dislocation, and it gives her no inconvenience.

Given this condition *in utero*, slight causes would suffice to dislocate the head of the bone. If this occurred early in intra-uterine life, the child would probably be born with congenital dislocation and an undeveloped or absent acetabulum.

If the head of a bone has long been dislocated, the surgeon finds, when he performs an excision, that the joint itself is filled with new material. I have observed this in the excision of the shoulder-joint, performed for old dislocation of only six months' standing.

If a dislocation occurs in a rapidly-growing fetus, on account of hereditary causes (a long relaxed ligament), or by violence in childbirth, and the deformity is not discovered until the child begins to walk at the age of fifteen months, it should be expected that the acetabulum would be absent or undeveloped.

To summarize: Congenital dislocation of the hip is produced, I believe, by injury at birth; injury *in utero*, or disease *in utero*; rachitis; hereditary influences, and, in exceptional cases, if such there are, by arrest of development of the acetabulum.

TREATMENT. — The treatment is divided into mechanical and operative. Complete excision of the joint has been performed, and good results reported.

Cutting down and making a new acetabulum in the dorsal of the ilium, and nailing the head of the bone into it, has met with some favor.

These two operations are advisable only in adults or in children over seven or eight years of age.

The operation of Hoffa, of Würzburg, in small children seems to me the most rational one to perform. He makes an incision down on to the head of the bone; scoops out the acetabulum, cutting deeply into the bone, and reduces the head to its normal condition. He claims excellent results from this.

The operation is not performed on children over five years of age, and where it is an impossibility to pull the bone down to the old acetabulum.

Operations of this magnitude are serious, and must be attended with considerable mortality. Still, the results of mechanical treatment in the past have been so discouraging that the surgeon now feels justified in performing any of the operations which promise satisfactory results.

The mechanical treatment of hip-joint disease has always been unsatisfactory, until the case of Dr. Buckingham Brown, of Boston, was reported. This case was perfectly cured, with perfect motion, without shortening. It was treated in bed for two years by extension, and great care in manipulation.

The French have long treated their cases in bed, and have reported very good results. They have also

devised very ingenious appliances for making extension and still allowing their patient motion of the hip-joint. After the patients have been treated for a length of time in bed, they are allowed to exercise in a wheel-chair.

Adams improved upon this method of long confinement in bed, by devising a bed in which extension could properly be applied and the limbs held in the normal position. In this, the patients could be carried into the open air daily. This is simply a form of portable bed.

Sayre and Taylor, in fact nearly all of the American orthopedic surgeons, have treated such cases with the long traction hip-splint: but I must say, judging from my own observations and those of others, that the results of this plan of treatment have been most unsatisfactory. The patient would wear the splint for years, and when removed there would either be a relapse, or one limb would be found to be considerably shorter than its fellow.

I believe that the treatment of congenital dislocation of the hip should be divided into three stages:

- (1) The period in bed.
- (2) The period with the long fixation splint with a lateral-pressure screw. (See Fig. 5.)
- (3) The period with the walking-splint.

FIG. 5.

The patient is never allowed, during this stage of treatment, to step upon the brace, but after a year, or

FIG. 7.

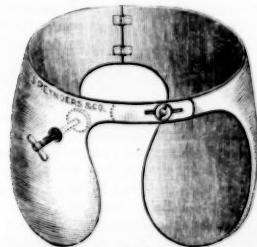

FIG. 6.

The length of the period of bed-treatment should continue until the limb is drawn down to the length of its fellow, if possible. During this treatment by extension, the patient is put into steel breeches (see Fig. 6), which has a lateral-pressure screw fitted to a pad, which makes pressure over the great trochanter: the object being to excite a certain amount of irritation, which will result in the growth of new tissue around the head of the bone.

After the limb has been drawn down to its normal length, which will take usually from two to six months, the patient is put on crutches, with a high shoe and fixation-splint, with lateral pressure, as seen in Figs. 5, 7.

a year and a half, the upper part of the brace is cut off, the high shoe is lowered, and the patient allowed to walk upon the splint.

Small children I treat with the plaster-of-Paris portable bed.

TWO CASES OF RUPTURED UTERUS TREATED EXCEPTANTLY.¹

BY EDWARD REYNOLDS, M.D.

MRS. X., an out-patient of the Boston Lying-in Hospital, had been in labor about eighteen hours when I was called to her on July 24, 1886. The head was extended across the brim, the os was about the size of a dollar, the pains were almost unintermittent, and the uterus was in a state of tonic contraction. The condition had not been considered important, and I was merely sent for on account of lack of progress. I etherized the woman, and introduced the hand to flex the head, but with considerable anxiety, on account of the tonic condition of the uterus. At almost the first touch, before I had made more than a tentative effort, and before I had used as much force as is ordinarily requisite, there was an audible snap, the head receded from my touch, and the cord prolapsed. On passing the fingers through the os, I found that the head and one shoulder had escaped from the uterus into the abdominal cavity through an extensive longitudinal rent in the right lateral wall. The cord was pulsating, and the feet were easily accessible; in the interests of the child, I dilated the os manually, delivered by version, and removed the placenta and membranes manually from the uterine cavity. I then asked Dr. C. M.

¹ Read before the Surgical Section of the Suffolk District Medical Society, December 2, 1891.

Green to see the case with me; in the meantime administering stimulants subcutaneously on account of the severe collapse which almost immediately followed the rupture.

On Dr. Green's arrival, we carefully examined the uterus, and found that the rent extended from the cervico-corporeal junction about half-way to the fundus, but that it had not been prolonged into the cervix during the delivery of the child. There was no hemorrhage of moment; and although the woman was by that time beginning to react from the primary shock, we agreed that her weakness forbade us to think of removing her to a hospital, and that the surroundings, which were those of a filthy tenement house, rendered laparotomy so far inadvisable that it was better to entrust her to the chances of conservative treatment. Within the next few hours she rallied from the shock, and during the next few days underwent a somewhat severe peritonitis, which was treated by opiates. She became progressively more and more weak; and although on the sixth and seventh days after the accident the peritoneal inflammation appeared to be decreasing, she failed, and died, apparently of exhaustion, on the eighth day. There was undoubtedly some septic infection. The child did well. I think now, as we both thought then, that the case was one which under better circumstances should have been treated by laparotomy.

The second case which I have to report is one which I saw in consultation, and which for obvious reasons I am unwilling to substantiate by giving the residence of the patient, or the name of the gentleman with whom I saw it.

The patient was a primipara, and after a somewhat long labor without essential progress, the doctor did a manual dilatation and version, extracting a medium-sized child without especial difficulty. Failing to deliver the placenta by Crédé's method, he passed his hand into the vagina, and was horrified to find that his fingers passed readily through a large rent in the posterior cul-de-sac, and came into contact with the peritoneal surface of the posterior uterine wall.

On arrival, I made a vaginal examination, and assured myself that the posterior vaginal wall had been ruptured across Douglas's fossa at its junction with the cervix, almost from side to side. I recommended no active treatment, other than scrupulous asepsis, which had already been observed during the labor; stimulants to counteract the primary shock, which was not extreme; a liquid, supporting diet; and the free use of small but repeated doses of sulphate of magnesium. I saw the patient several times during her convalescence. She underwent a fairly severe general peritonitis, but was never in a condition which I considered dangerous, and made a prompt recovery. She came to my office about three months later, at my request, for a pelvic examination. She was at that time the picture of health, and complained of no pain or other symptoms. On bimanual examination, I could detect no abnormality of the pelvic organs, other than a readily recognized cicatrix in the posterior cul-de-sac of the vagina.

Though this was properly a case of rupture of the utero-vaginal attachments and not of the uterus, the conditions involved are so closely similar that the distinction seems to be technical rather than essential.

In addition to these two cases I have had the opportunity of seeing two others, both of which recovered without treatment. Of these I will not speak in detail

as I hope that Dr. Green, in whose care they were, will report them himself to-night. My own experience with this accident thus consists of four cases, all treated without laparotomy, of which three recovered, while in the fourth, the only fatal case, circumstances prevented the method of treatment which was really indicated, that is, laparotomy.

I have made no attempt to review the literature of the subject, but before entering upon a general discussion of the question, I wish to quote from the first number of the *New York Journal of Gynecology and Obstetrics*, two very remarkable cases which have a distinct bearing upon the question.

In the course of a discussion upon intra-abdominal hemorrhages in the New York Obstetrical Society, Dr. J. R. Goffe said that "an interesting case had come under his observation last summer, at Randall Island Hospital, in a woman who had been confined four months before, the labor having been a difficult and unsided one. While she was etherized for perineorrhaphy, he carefully examined the pelvic organs, and found that the sound passed directly through the uterus, and could be felt directly beneath the abdominal walls. The uterus was retroverted. Upon dilating the cervix and passing the finger into the uterus, the opening was found to be an extensive rent obliquely across the face of the uterus, reaching from the left horn to the intertus os. There was no history to account for it, but he supposed it must have occurred during labor." This was the second case in which the speaker had found an opening through the uterus. The first occurred in a woman who presented herself at the clinic of the Woman's Hospital, and was seen at the same time by Dr. Cleveland. In that case, they could pass the uterine sound without any force directly through the uterus up to the umbilicus. The opening was not as large as in the one that he had seen the past summer.

When to these cases of my own are added the numerous instances of recovery without operation which I have chanced to see in the course of general reading during the last six years, I can but disagree heartily and entirely with the statement which is so often made, that laparotomy and suture of the rent is indicated in every lacerated wound of the uterus.

I am glad to have an opportunity of speaking upon this subject, because it is one in which I have been led to take an active interest by the experiences to which I have referred, and also because the opinions to which that experience has led me are in considerable contrast to those which we have just heard; and, as I believe that such discussions as this to-night are most profitable if each speaker outlines briefly the views to which his experience has led him, in order to afford an opportunity for the development of both sides of the question, I think it may be permissible for me to occupy a few moments more with a brief statement of the principles by which I should now expect to be guided if any case of this nature should present itself to me.

This accident exposes its victim to three dangers, and to three only; namely, to the exhaustion of primary shock, and to the dangers of hemorrhage and peritonitis.

Primary shock, though rarely fatal, is usually well marked; and is sometimes so severe that it might well be sufficient to cause death in a feeble woman, or in one whose heart was already organically unsound. It

is always an element of importance in estimating the method of treatment which should be employed.

Hemorrhage, though often fatal in untreated cases, must, I think, be much less frequent than has been supposed, at least, in its severer forms. So far as I am aware, its appearance or non-appearance cannot be predicted from the situation or extent of the rent. While there can be no doubt that in the face of persistent progressive hemorrhage, laparotomy and suture of the rent offers the only possible chance of life to the patient, the diagnosis of the presence or absence of hemorrhage is unfortunately by no means easy, and I should certainly agree that in the presence of any question upon this point the patient should be given the benefit of the doubt and subjected to laparotomy. In making this diagnosis our chief reliance, apart from physical examination, must be placed upon the duration of the primary shock. Under the subcutaneous use of stimulants, and the application of artificial heat, the patient ordinarily recovers promptly from shock unaccompanied by hemorrhage. In consideration of the fact that there have probably been but few cases in which laparotomy was performed within an hour after the occurrence of the accident, I should be inclined, in the absence of distinct evidences of hemorrhage, to wait at least an hour after reaction, before assuming its presence.

In many cases, however, it is possible to obtain important information by passing the fingers through the rent, in order to ascertain the presence or absence of considerable clots in the peritoneal cavity; and if this is done with proper gentleness and with due care to minimize the amount of manipulation, I can hardly think that it would add to the shock in degree sufficient to contraindicate the manoeuvre.

In the absence of hemorrhage, the one danger to which the patient is subjected is that of death from peritonitis; and the question in such cases resolves itself into the inquiry, what is the best treatment for peritonitis of either mechanical or septic origin in the presence of a lacerated wound of the uterus? Two elements in the situation must be considered in answering this question; and I think that it is best to consider each separately.

When the circumstances and previous conduct of the case are such that but a small quantity of, presumably aseptic, material can have entered the cavity of the uterus, I can see no advantage in an immediate laparotomy; but should be content with supportive treatment and the administration of Epsom salts, in the manner recommended by Mr. Tait, when the first abdominal tenderness appears; but in the case of a patient who is in good condition and not markedly collapsed, I should be inclined to begin its cautious administration at once, in anticipation of the peritonitis which is almost certain to follow, in some slight degree, at least.

My view of the proper treatment of these cases is founded mainly upon my experience in the treatment of septic peritonitis, in the out-patient clinic of the Boston Lying-in Hospital. Although in that clinic the death-rate from sepsis has of late years been reduced to a scarcely appreciable fraction of one per cent., the conditions under which the work is done have as yet prevented us from wholly excluding the disease in its minor and medium degrees of severity; but, although we are confronted several times each year with septic peritonitis of more or less severe

grade, we have, since the adoption of the open treatment as a routine measure, nearly four years ago, lost but one patient from this cause; and in that one, the onset of the disease was so extremely severe, that within forty-eight hours after the first symptoms she had developed metastatic abscesses, and died of pyæmia on the succeeding day.

In the light of this experience, I cannot believe that the degree of peritonitis which is likely to be caused by the retention within the abdominal cavity of a small amount of aseptic blood, or even of aseptic lochia, is likely to afford a sufficient risk to compensate for the added dangers of laparotomy.

When the circumstances of the case are such that a large quantity of clean foreign material, or an even small quantity of presumably septic fluid, has obtained entrance to the abdominal cavity, I think that the choice of treatment must depend upon the extent and situation of the rent. It seems to me that the only advantage to be gained from laparotomy, so far as the immediate preservation of life is concerned, is gained by the opportunity which it affords for cleansing the peritonitis by the injection of large quantities of warm water; and I contend that when the rent is large and accessible, and so situated as to afford fair drainage, it is better adapted for this purpose than any wound in the abdominal wall can possibly be. I should then in such cases content myself with flushing out the cavity through the wound, taking care to provide an adequate return for the injected fluid; and should resort to the insertion of a drainage-tube or a Miculitz gauze drain, in any case in which this seems to be indicated by the other circumstances of the case. When in the presence of probable septic infection, or of a large amount of foreign material in the peritoneal cavity, the wound is small or in an inaccessible situation, I should unhesitatingly resort to laparotomy, and should then seize the opportunity for the incidental advantage in after life which I believe to be afforded by accurate suture of the uterine wound.

Cases of incomplete closure of the wound, such as those reported by Dr. Goffe, are probably extremely rare, and in such cases, I myself believe that it would be as well for the patient to undergo a subsequent laparotomy for the closure of the rent, rather than to submit to the operation in the presence of shock, and in the face of the other disadvantageous circumstances which usually accompany an accidental rupture of the uterus.

In conclusion, I would then advocate laparotomy in the presence of persistent hemorrhage, and in cases where the rent is small or inaccessible, and the quantity of foreign material introduced into the peritoneal cavity excessive, or of a septic character; if the irritation of the peritoneum has not been excessive, I would content myself by flushing out the abdomen, if possible; I should be satisfied with supportive treatment and the use of saline cathartics in all other cases. The use of these latter remedies I should of course advocate in all cases, whether operated upon or not.

It will be seen that the case which Dr. Haven has reported falls within the class for which I should recommend laparotomy, and I congratulate him heartily upon his wisdom and success in its management.

DR. WILHELM KRAUSE, who has been Extraordinary Professor of Anatomy in the University of Göttingen for thirty years, has resigned his chair.

RUPTURE OF THE UTERUS, WITH THE REPORT OF A CASE.¹

BY GEORGE HAVEN, M.D.

RUPTURE of the uterus, and particularly of the non-pregnant organ; is such a rare and at the same time such a serious accident, that I have deemed the following case sufficiently interesting to present for discussion this evening. I am obliged, in order to give a clear idea of the case, to briefly sketch the history before rupture occurred.

Some time ago I was asked to see Mrs. E., six months pregnant, and eclamptic. The convulsions began at six o'clock, A.M., and continued at intervals of about thirty minutes until eleven o'clock, when she was chloroformed, and the os uteri dilated manually. I saw her at one o'clock, and after a short time delivered her. She was put in a steam bath, given croton oil, etc., and made a perfect recovery. Ten days later, she had a slight hemorrhage, which was followed in five days by a second. Shortly after this I saw her again. She was very much blanched, with a rapid, thready pulse. A small amount of placental tissue, was removed with the curette, in all about a tablespoonful. She was given stimulants and ergot.

Everything went well from this time for a month, when she had a hemorrhage, which in sixteen days was repeated. At this time Monsel's solution was injected. Shortly after this I saw her. Pulse 150, and very weak; lips and finger-nails white. Ether was given, the patient placed in the Sim's position, and the curette introduced, without difficulty after the proper curve had been established. The left uterine wall was explored first, and everything found apparently normal. The curette was then turned to explore the right cornu, when without force and to my dismay, it entered to the handle. The uterus was now examined bimanually, and found small and apparently hard. The patient was placed in bed, brandy given subcutaneously, and arrangements made to bring her to Boston, which was done the following morning. Dr. J. W. Eliot saw the case in consultation. The finger introduced into the uterus felt several grooves, running towards the right cornu; and a sterilized sound introduced into the cavity was clearly felt at the level of the umbilicus. A rupture of the right wall of the uterus was thought to be present, and laparotomy advised. At three o'clock in the afternoon, or twenty-four hours after the rupture was first discovered, with the assistance of Drs. Mumford and Cobb, I opened the abdomen by an incision in the linear alba, two and one-half inches long. The uterus was easily brought into view, and a ragged rent was found extending from the right cornu almost down to the internal os, anterior to the broad ligament. The edges of the rent contained several white centres, which looked like spots of necrosis. A V-shaped piece was excised, leaving a clear wound, in what appeared to be normal uterine tissue. The edges were united by four deep silk sutures, going through the muscular wall, and three superficial ones, drawing as well as possible the peritoneum over the wound. The abdomen was then flushed with boiled water, at about 110° F., for two reasons: first, because of its effect upon the pulse; and, second, to wash out any fragments or clots. The abdominal wound was closed with four silver-wire sutures. The patient was put to bed surrounded with hot bottles; brandy was given subcu-

taneously, as well as by enema. The pulse after the operation was about 160 and weak. An injection of salt solution was thrown into the rectum, but did not remain long enough to be absorbed. After one of the earlier hemorrhages, this was found of great service. The pulse on the third day fell to 125, the temperature never went above 101.2°; and on the twentieth day, the temperature was normal, with a pulse of 100. She remained five weeks at the hospital, then returned to her home. I saw her a few days ago, and found everything in excellent condition. Color has come back to her cheeks; the uterus was firm, small and in good position.

There are two good reasons for resorting to laparotomy in all cases of uterine rupture; namely, the danger of sepsis and the possibility of hemorrhage. The first we may have guarded against, and, to a certain extent, be able to exclude. The latter we can never feel quite sure of when we realize that the uterus is practically an erectile organ; that because it is well contracted at one time is no proof that the contraction will remain; and if it should become relaxed, hemorrhage of great volume can take place, either through the cervix and so externally, or internally, causing a fatal termination.

One other thing is worthy of thought in the case reported; namely, the ragged condition and necrotic appearance of the rent. It was certainly not a wound which would have healed kindly by first intention; an abscess might have formed which at best would have delayed recovery, and been a serious matter for the patient, reduced as she was by hemorrhage; the peritoneal cavity might have been flooded by pus, when the result would probably have been fatal.

I find one case reported in the *British Medical Journal* for October 17, 1891, page 382, where, after puncture, a pint of corrosive solution was injected into the abdominal cavity through the opening in the uterus; the patient dying in the course of three days from sub-limate poisoning. Could this life not have been saved by a laparotomy and proper flushing of the abdominal cavity? Statistics are at best disappointing, so many avenues for error are open.

The title of the paper not limiting me to the simple report of a case, I wish here to incorporate a few tables relating to rupture, etc., in the parturient uterus. First, as regards the frequency of rupture, Dr. Riedinger of Prague reports five cases in 2,005 births; Spiegelberg, one case in 3,000 births; and Leopold, five in 6,100. These tables are of later date than those compiled by Ames in 1881, when he gave 20 ruptures in 99,796 cases or one in 4,990. All these, taken together, give a total of 31 cases of rupture in 110,901 cases, or one rupture in about 3,575. The only cause for error in this calculation is that the English statistics are of a much better showing than the foreign, possibly due to the greater frequency of contracted pelvis among the German population. This great difference will be shown from the fact that at the Royalty Maternity, London, and at Guy's Hospital, there were but 17 cases of rupture in 92,796 cases, or 1 in about 5,500. Winckel gives an interesting table of mortality from tears occurring in different situations:

	Location of Rupture.	Cases.	Recov.	Per cent.
1. Fundus	5	3	=	60
2. Anterior wall	37	17	=	34
3. Posterior wall	8	4	=	50
4. Side	11	3	=	27.3
5. Circular	2	1	=	50
6. Cervix	18	9	=	50

¹ Read before the Surgical Section of the Suffolk District Medical Society, December, 1891.

Bandel states that all tears begin in the lower uterine segment, and extend upward. The greatest number of recoveries, according to this table, have occurred when the tear was situated in the fundus, the next best situation being the posterior wall. Winckel has never known a case to recover where the tear extended into the fornix vaginae. The uteri ruptured, have in almost every instance, been those of multiparae; and in ten cases which I have been able to collect occurring since 1885, I find that but one took place during the first pregnancy; three in the second, four in the fourth, one in the sixth and one in the seventh.

There are those who still strongly advocate an expectant method of treatment, namely, drainage, tight abdominal bandage, and in some cases massage; and on the other side, there are those who believe that the abdomen should be opened in every case. We must not forget that there are complications which may make either method a failure; as, for example, first, the escape of a macerated fetus through the tear. In eight cases of this kind, three only recovered. Second, where the fetus has partly escaped, and an attempt is made to remove it through the natural channel, the tear is often enlarged, and the prognosis consequently more unfavorable. The third complication is where the gut prolapses through the tear into the vagina. In many cases which have come to operation, hours have elapsed since the rupture occurred, the patient has lost much blood, and is suffering from profound shock. Given a case where the tear is discovered almost as soon as it occurs, and I think there is very little doubt that laparotomy is indicated, especially since the improved Cesarian section has taught us how to suture the uterus. The nature and seat of the tear will have to be considered. Haemorrhage is first controlled by the ligature, or forceps. If the tear is low down in Douglas's fossa, and of not very large extent, drainage into the vagina may be employed. If, on the other hand, the tear is fairly clean and occurs either on the fundus or upon the anterior or posterior wall, the edges may be trimmed and united with deep and superficial sutures. If ragged and large in extent, especially if extending from the fundus well down to the cervix or into it, the uterus had better be removed, by amputation, if enough of the cervix remains to form an extra-peritoneal stump; the mortality being great where the stump is dropped back into the abdominal cavity. If this is not the case, the whole organ had best be removed. Coe thinks that in cases where the tear is incomplete, and where hemorrhage has taken place in the broad ligament, there is still some doubt regarding the treatment. These are cases which I think can safely be left to nature, and the less we meddle with them the better. I have found notes of ten cases which, so far as I know, have never been tabulated. Eight were treated by laparotomy. Of these, four recovered and four died. One of these cases, however, was complicated by the escape of a macerated fetus into the abdominal cavity, so that I think it is only fair to exclude this one from the number. If this is done, we have four recoveries and three deaths. Two were treated by drainage. One lived and one died. The uteri in the cases operated upon were all treated with the Seenger stitch, silk being used for ligature; and in this connection, it seems only fair to include Winckel's cases, where ten out of fourteen recovered, all treated by laparotomy.

In conclusion, it appears to me that in cases of

rupture of the uterus, both in the pregnant and non-pregnant variety, our best course is to open the abdomen, wash out the abdominal cavity and unite the tear by deep and subserous stitches, in all cases where it does not involve too much uterine tissue, or where the edges are not too much bruised and torn. Punctured wounds, as those made by the sound, for instance, can very properly be left to nature. The autopsy table has shown many uteri bearing scars from punctured wounds which occurred during life and gave no trouble.

In considering this subject, we must not forget the great advance which has been made since Seenger's first article on the improved Cesarian stitch. That we can open the parturient uterus, remove the fetus and sew it up again without to any great extent endangering the patient's life, is, I think, a pretty generally accepted belief.

As regards the material best suited for ligatures in this operation, I think that silk takes the first rank.

There are in the October number of the *American Journal of Obstetrics*, several cases of Cesarian section reported, where the operation had been performed from two to three times upon the same individual, in some of the earlier operations, silver-wire having been used to bring the uterine surfaces together. It was found in position and in perfectly good condition; but the scar was not so firm as that found in cases where the silk had been used. The same may be said of catgut.

THE FROG AND THE PHYSIOLOGIST. — In his Christmas lectures at the Royal Institution in London, Professor McKendrick spoke of the services which frogs have rendered to the cause of physiology, and suggested that a statue of a frog be erected as an acknowledgment of the many benefits which the race of frogs have indirectly conferred upon the human race.

**REMOVAL OF A CANCEROUS UTERUS BY
VAGINAL AND ABDOMINAL HYSTEREC-
TOMY.¹**

BY ERNEST W. CUSHING, M.D., OF BOSTON.

The operation of vaginal hysterectomy for cancer is now so well established as a comparatively safe and thoroughly useful operation, and the technique is so well understood, that descriptions of simple cases are no longer of particular interest. Various complications may arise, however, such as impaction of the vagina or broad ligaments in the disease, inflammatory adhesions of the uterus or appendages, or disproportion of the size of the body of the uterus to the capacity of the vagina, which may either contraindicate the operation or make it so difficult and hazardous that it is not easy to decide whether it should be performed or not.

The case which I have to report to-night belonged to the latter category, and presented several features which make it worth reporting, and render it valuable as a means of establishing certain conclusions, and in aiding the formation of a decision as to what course is to be adopted in similar cases.

The history is as follows: The patient is thirty-seven years of age, married. She was brought to the Charity Club Hospital by Dr. Blazo, of Rochester, N. H. She had always enjoyed good health until nine months before entering the hospital, when she began to suffer from a sharp pain in the side, and had an acrid and watery vaginal discharge, which has lately increased. There is pain in the back, left side and leg, so that she cannot sleep. She is very nervous and has had to take morphine on account of the pain. The discharge is now bloody and offensive. Five months ago an operation was performed for removal of a cancer from the cervix uteri. This operation only gave temporary relief to the symptoms. The fundus uteri has enlarged considerably during the last few months. Owing to repeated hemorrhages which have occurred lately, the patient is quite weak, though able to be about her room part of each day.

On examination it was found that the cervix, or what remained of the vaginal portion, was cancerous, the disease extending to the posterior fornix of the vagina at one point, elsewhere seeming to be limited strictly to the uterus. The broad ligaments were not implicated. The uterus was freely movable but the body was enlarged to the size of a fist, so that it was very doubtful whether it could be delivered through the vaginal opening.

All things considered it was determined to remove the cancerous cervix at any rate, and to extirpate the whole organ if the conditions found on operation and the strength of the patient should permit.

The cancerous tissue was first scraped away with the spoon-saw, the bleeding checked by packing the cavity of the cervix, and the field of operation thoroughly cleansed. The cervix was drawn down by threads passed through it and by forceps, and the customary incision carried round it. This was a matter of great delicacy posteriorly, as it was necessary to carry the incision below the limit of the disease in the posterior fornix, and to dissect carefully in order to avoid the rectum. This took some time as the parts were vascular and it was necessary to control all

hemorrhage with stitches and ligatures, since the patient was in no condition to lose much blood. The broad ligaments were secured with ligatures in order to have as much room as possible for extraction of the fundus. This took so much time, however, that I finally put a clamp on each side, thus securing all except the upper portion of each broad ligament.

It now became evident that the uterus was so long that these portions could not be reached without retroverting the uterus, which was impossible on account of its size. It could not be drawn down sufficiently to split it in halves, as the peritoneal insertion was very high up, both over the bladder and posteriorly.

The patient's condition was excellent, and the quickest and safest thing to do seemed to be to open the abdomen to remove the rest of the uterus. This was done at once, the diseased portion of the uterus having first been amputated and the vagina well cleansed as well as the hands of the operator; fresh instruments and sponges were employed, such as would be used in any abdominal section.

The patient lay, however, in the lithotomy position. The abdomen being opened the fundus was drawn up easily with bullet forceps. A clamp passed into the vagina was made to grasp the remaining portion of the left broad ligament, which was then severed. A chain stitch of catgut was then made to include the tissue between the anterior surface of the uterus and the bladder, as well as the remaining portion of the right broad ligament. The fundus was removed, the pelvis well irrigated with hot Hygeia distilled water, and a twist of iodoform gauze, as large as the wrist, was drawn from above down through the vagina. The abdomen was then closed, not having been open over ten minutes.

The patient was put in bed in good condition; the gauze drain carried away all the irrigation fluid. There was no hemorrhage and the patient rallied well. The day after the operation all seemed favorable except that the pulse was rather rapid and intermittent. The second night, however, symptoms of heart-clot supervened. Precordial pain, anxiety, rapid intermittent pulse, rapid breathing, and towards morning vomiting of gastric fluid.

The second morning the clamps and gauze were removed. The abdomen seemed to be quite in order, no pain nor distension. Temperature 102°. The pulse however, was rapid and feeble, and could not be felt after nine o'clock. Some vomiting still; cardiac distress; pulse in carotids, 180. Death at noon, forty-seven hours after completion of operation.

Autopsy.—No signs whatever of sepsis or peritonitis; no fluid nor lymph in peritoneal cavity. Intestines had adhered together sufficiently to roof over the site of the pelvic operation. Kidneys normal. In the heart, beginning at the tricuspid valve, there was a firm clot, interlacing with the muscles and tendons of the valve. This clot extended through the opening of the pulmonary artery, and followed the bifurcations of this vessel, as is seen in the specimen here presented, to the fourth or fifth bifurcation, so that it ends in long fine tufts, forming a complete cast of the lumen of the pulmonary artery.

The uterus herewith presented shows very distinctly the cancerous disease of the cervix and the impaction of the posterior fornix. The enlargement of the corpus was due to a nodule in the anterior wall, about one inch in diameter. What this was, of course, could not

¹ Read before the Surgical Section of the Suffolk District Medical Society, December 2, 1891.

be determined during the operation, and was not sufficiently clear even on incision of the specimen. Under the microscope it appears to be a sarcomatous nodule, and such is the opinion of Dr. Whitney, who has kindly examined it. I have here very fine microscopic slides, prepared by Dr. S. P. Cottrell, showing the nature of the disease of the cervix and of the nodule in the fundus. The one under the microscope is for the examination of members of the Society.

Of course, the fatal termination of this case leads to a consideration of the causes of this result, and of any means which could have been used to prevent it.

Heart-clot or thrombosis of the pulmonary artery is not a very rare complication of operations when the blood of the patient has been impoverished by long suppuration or by continued hemorrhages. It is thus peculiarly liable to follow hysterectomy for grave cases of cancer, or for myoma, when this has led to much hemorrhage.

The obvious conclusion is that the operation should be performed early, before the system is exhausted and the blood is impoverished. It is a very unfortunate and unpleasant position for the surgeon to have to choose between refusing his aid to a patient, who without it is doomed to certain and painful death, or, on the other hand, operating when he plainly sees that the chances are unfavorable, owing to delay. The consensus of operating gynecologists is strongly in favor of early operations in all cases which will have to be operated on eventually, and in this respect there is little doubt that the profession and the public will gradually be educated into the same position in regard to pelvic inflammations and myomata of the uterus, which they are now holding in regard to ovarian tumors. In regard to carcinoma uteri, however, the case is much stronger, every day of delay increases the risk of relapse, and may increase the difficulty and risk of operation. There is practically no danger in vaginal hysterectomy if done early and while the patient is in good condition, provided the operation is done properly and the subsequent treatment is judicious.

When in Berlin, in 1885, I heard Martin declare that in his opinion the proper treatment for all cases of cancer of the uterus in the early stages, was vaginal total extirpation of the uterus. I was astonished, but time has shown that his position is the right one, and I think it will now be endorsed by those modern operators who have studied the question thoroughly and are free from preconceived opinions on the subject.

In cases, however, like the one here presented, where the patient is weakened from hemorrhage and discharge, it is sometimes well to do a preliminary operation for removal by the spoon-saw and cautery, of as much of the diseased tissue as possible, and this I have done in several instances with the happiest results. The absorption of septic matter is thus stopped, hemorrhage ceases, opportunity is given for systematic nutrition, and after two weeks the major operation can be performed with better prospect of success. The disadvantages of this course, however, are the increased danger of relapse, owing to longer presence of the disease, and also the disqualification of the patients to undergo two operations when one might answer. In hospitals, also, where surgical work is done which must be clean and aseptic, it is not safe or right to other patients to have among them a case

where the uterus is cleaning up after curetting and cautery. Of course, this objection is of less force where proper isolation of such unclean cases can be had.

In the case reported I judged it wiser not to delay as the disease had reached the extreme limit where extirpation was possible, and as I feared further spread of the disease both in vagina and fundus, while during the operation no signs of shock were noticeable. In regard to the removal of the cancerous uterus by means of an abdominal incision, it is well known that Freud's operation was so fatal as to be abandoned, but the cause of the mortality is easily found in the fact that all the steps of the operation were done from above, and then the anterior and posterior edges of the wound were united, making a long, difficult, tedious operation, without systematic drainage, and where the circumstances of the case were such that the peritoneal cavity was pretty sure to be infected. It is far easier and quicker, however, to remove the fundus only from above, after all the lower parts of the broad ligament had been severed from below, and the separation of the uterus from the bladder has likewise been largely entirely accomplished from the vagina. This method is applicable to cases of hysterectomy for myoma as well as for cancer; the compression of the broad ligaments by a clamp introduced from the vagina, as described above, was first performed by a surgeon of Brooklyn, N. Y., and is a rapid means of enabling the uterus to be brought up. In cases of hysterectomy for myoma or more particularly for sarcoma of the body of the uterus, where it is thought desirable to remove the whole of the cervix, the operation may be commenced and finished from above, or when the upper part of the broad ligaments has been tied off, the cervix may be encircled with a rubber constrictor and divided above the latter, when the stump can be surrounded with iodoform gauze and replaced at the bottom of the pelvis, the rest of the operation being finished from below.

The question of the best method of removal of the whole of the uterus, where it cannot be done by vaginal hysterectomy, is a very important one, and one which is under active consideration and discussion at the present time, but it cannot be adequately treated within the limits of this paper, which has been written merely to record one case, as it is only by the consideration and comparison of a large number of such operations that we can decide as to the best manner of treating such difficult and dangerous conditions.

Clinical Department.

CYST OF THE PANCREAS, TREATED BY LAPAROTOMY; DRAINAGE; RECOVERY.¹

BY M. H. RICHARDSON, M.D., AND J. G. MUMFORD, M.D.

THIS case is interesting as showing an unusual condition coincident, but not associated with already existing disease.

The patient, Mrs. B., referred to Dr. Richardson by Dr. Cox, of Holyoke, was a robust woman of thirty-eight, with an excellent previous and family history. She was married at the age of nineteen, but

¹ Read before the Surgical Section of the Suffolk District Medical Society, December 2, 1891.

never became pregnant. Up to the age of thirty-four her catamenia were painless and regular, every twenty-eight days.

Four years ago menorrhagia became noticeable, and increased in frequency for a year, when she sought medical advice. Two years ago she thought herself well, after the prolonged use of galvanism. A few months later, however, flowing returned, this time accompanied by the familiar train of symptoms which had not previously been prominent,—backache, headache, “bearing down” and frequent micturition.

By physical examination the uterus was found in the first degree of retroversion, enlarged symmetrically, about the size of a large orange, four and one-half inches in depth, the endometrium friable and bleeding easily. The patient's general condition was good; for the menorrhagia, though of ten days' duration each month, was inconsiderable in amount. Rest in bed, two thorough curettings and tonic doses of ergot and bromide of potash enabled the patient to consider herself well and to go about her household work after three months. This was January, 1891. Mrs. B. thinks that until about the 1st of May she had no further pelvic disturbance.

About the 10th of February, however, she had an attack of vomiting with pain in the epigastrium and for a month eating was followed by nausea. About the 1st of March she noticed a slight swelling in the region of the stomach, rather to the left of the median line. The swelling increased to the size of a small coconut. The pain seems to have been not excessive, though the patient appears to have taken much morphine. There was constant *malaise*, loss of appetite, dimness of vision, and morning headache with some constipation.

About the 1st of May the tumor entirely disappeared. The relief was temporary. The swelling returned slowly, and on the 1st of July, appeared to be two to three times the size of a child's head.

During these last three months, also, the uterine disturbances returned, and when admitted to St. Margaret's Home, the patient was suffering from a profuse hemorrhage. Small doses of ergot and iron controlled the flowing after a few days, and the pelvic disorders were, for the time being, disregarded, an examination of the uterus and annexa showing no material change from the conditions existing nearly a year previously, except that the uterus itself had become much diminished in size.

The woman's general appearance was at no time bad, and there seemed to have been no great loss of flesh. Restlessness, lack of appetite and constipation besides genuine acute epigastric distress, were alone the noticeable symptoms.

In the upper part of the abdomen was a tumor centered about three inches to the right of and above the umbilicus, egg-shaped, eight and one-half inches long by five inches at greatest appreciable breadth, smooth, movable, tense, not adherent to the skin, fluctuant, not tender or painful on moderate pressure. The patient had at no time been jaundiced, the stools had been normal in appearance, the urine was not in any way abnormal. The liver was apparently crowded slightly upwards, but not enlarged. There was no increase in the area of stomachic tympany, nor had the symptoms for several months pointed to a gastric disturbance. The question of exact diagnosis could not be settled by any evidence so far obtained. Cer-

tainly the patient was suffering great pain and discomfort from a cystic tumor of large size in the right hypochondrium and epigastrum.

An exploratory abdominal section was decided upon, and performed by Dr. Richardson, assisted by Dr. Mumford, July 28, 1891. The incision was made as if for cholecystotomy. The cyst, thin-walled, non-adherent, and but slightly vascular, was reached and tapped. One and one-half gallons of fluid, as described in Dr. Whitney's report, were drawn off. When this was withdrawn there remained a deposit of grayish-looking, greasy material, not unlike cheesy tubercular glands in appearance, lining the cyst wall.

The depths of the cyst were explored with the finger, which followed easily down behind the stomach, towards the left, to the middle of the pancreas, its broad pedicle being intimately associated with that organ. The operation was carried no further. Considering the feeble condition of the patient and the extensive attachment to so vital an organ, it would have been highly injudicious to have attempted enucleation of the cyst. Its walls were therefore stitched to the abdominal parieties, the cut in the cyst left open, and syphon drainage established.

The subsequent history of the case was uneventful. As in all similar conditions, the closing-in of the cyst cavity by granulation and adhesion was slow, but at the end of six weeks the patient went home well, except for a sinus which discharged daily about half a teacupful of clear fluid.

The long confinement in bed, together, perhaps, with tonic doses of ergot and iron, vastly improved the pelvic conditions. Two catamenial periods had been normal and painless, and the size of the uterus had sensibly decreased. Three months after the operation the wound had nearly healed, a slight sinus still persisting, and there was no return of symptoms.

Dr. Whitney's report was as follows:

“July 28, 1891. Fluid from the case of Mrs. B. There was said to have been withdrawn eight pints, by abdominal section.

“Thin, slightly opaque fluid with considerable pinkish sediment. Specific gravity, 1007; reaction alkaline; albumen one-fourth per cent.

“Microscopic examination showed normal red corpuscles; numerous leucocytes of varying shapes; a few larger cells with a distinct nucleus, nucleolus, and a clear protoplasm containing occasional oil drops. Small collections of oil drops (granular corpuscles) and numerous masses of thread-like filaments which did not stain with methyl blue on cover-glass preparations. These were determined by Drs. Fitz and Harrington to be crystals of stearine.

“The fluid emulsified fat, and changed cane sugar to grape sugar.”

There is no question but that the safest method of treating cysts of this kind is by drainage, without making any attempt at enucleation. It is obviously very difficult to dissect out a cyst which is in most if not in all cases caused by a dilatation of the canal of Wirsung or some of its branches. In the case of cyst of the pancreas, previously reported by Dr. Richardson,² the sinus became completely closed at the end of about ten months. The immediate effect of the secretion upon the skin is an irritating one, but by care this may easily be avoided. The discomfort of a persistent sinus is therefore not great. Bearing in mind

² See Boston Medical and Surgical Journal, Vol. xxiv, No. 5, p. 111.

the dangers which would attend the rupture into the epigastrium of a tense cyst of whatever origin, it is quite imperative that such collections should be investigated by early exploration, and treated in accordance with existing conditions.

NOTE.—January 23, 1892. Examination of Mrs. B. to-day, at her home in Holyoke, shows a vast improvement in her general condition. There still remains a sinus in the centre of the epigastric wound, kept open by a small piece of iodoform gauze, which discharges about half a teaspoonful a day. The fluid is perfectly clear. The skin is in good condition, having been protected by the use of oxide of zinc. The director goes in about two inches and a half. The abdomen is soft everywhere, and no tumor or swelling can be detected by physical examination. There seems to have been a diminution in the amount of discharge since the last report, three months ago. I advised removing the cotton in order to allow the sinus to heal, if possible. — M. H. R.

Medical Progress.

RECENT PROGRESS IN THE PATHOLOGY OF THE NERVOUS SYSTEM.

BY PHILIP COOMBS KNAPP, A.M., M.D.

MUSCULAR DYSTROPHY.

To the opening numbers of the new *Deutsche Zeitschrift für Nervenheilkunde*, Erb¹ contributes the most exhaustive monograph that has yet appeared upon this subject. The clinical types of dystrophies generally recognized are the "juvenile" form of Erb, beginning in youth, occurring in families, affecting primarily the muscles of the shoulder and upper arm, and often associated with true or false hypertrophy; second, the ordinary pseudo-hypertrophy; third, the "infantile" facio-scapulo-humeral type of Duchenne, recently described by Landouzy and Dejerine, and discussed in these columns;² and, lastly, the "hereditary" form of Leyden, beginning usually in the legs. Erb has collected nearly ninety cases, and a number of autopsies and reports of examination of excised muscles. He maintains the essential unity of these four forms. In the juvenile and infantile forms there is often pseudo-hypertrophy; in pseudo-hypertrophy there is often atrophy of the shoulder muscles: in both forms the face may be subsequently involved, all forms may be hereditary, and in the hereditary form the shoulder muscles may be involved. All forms agree in the characteristic attitude of the patient, the affection of certain muscles, the occurrence of hypertrophy and pseudo-hypertrophy, the absence of fibrillary twitches, and the simple quantitative diminution of electrical irritability. One or two cases are reported in which there was reaction of degeneration, but Erb himself has never seen it. Furthermore, transition forms are not uncommon: in the juvenile form the face may be subsequently involved, as it may in pseudo-hypertrophy; the infantile form may show "juvenile" localization or pseudo-hypertrophy; pseudo-hypertrophy may have later a juvenile localization, and all may be hereditary. Finally, forms may occur which cannot easily be assigned to any one of these four types. Another argument in favor of unity is that in one and the same family several of these types may be found. From the harmony in all the essential clinical features, from the occurrence of transition forms, and from the occurrence of several forms in the

same family, Erb therefore concludes that clinically these four forms are essentially one.

On the pathological side, Erb³ has collected the records of eighteen autopsies, and twenty-three examinations of excised muscles. He finds the characteristic changes to be hypertrophy of the muscular fibre, present in post-mortem examinations as well as in excised portions, and therefore not due, as Oppenheim and Siemerling have claimed, to the results of excision; atrophy of fibres; a change in the shape of the fibre, which loses its angles and becomes rounded; an increase of nuclei, with the presence of nuclei in the centre of fibres; fissuring and division of the fibres; and the formation of vacuoles. These changes occur in various combinations, but it is impossible to make any anatomical distinction between the four forms. In all, for instance, hypertrophy and fissuring may be rare or frequent, and the fibres may be equal or may vary greatly in size. The interstitial tissue is usually increased in amount, and a deposit of fat is common in it. In general this proliferation of connective tissue and fatty infiltration is pronounced in pseudo-hypertrophy, but it is also observed in the other forms, and some of the muscles in pseudo-hypertrophy show it only in a slight degree. The complete autopsies show, as a rule, that the nervous system is intact. The muscular changes are the same in these cases as are found in the excised muscles. Erb concludes, therefore, that we do not find in the different forms of muscular dystrophy any essential and comprehensive distinction in the histological changes in the muscles, and that these types form one morbid entity, dystrophia muscularis progressiva.

In discussing the pathology he considers that the changes in the muscular fibre are primary and essential, and that the connective tissue changes are secondary, for changes in the muscle are often found alone, but changes confined to the connective tissue are never seen. The muscular changes are hypertrophy, atrophy, increase of nuclei, vacuole and fissure-formation. Hypertrophy is regarded as a distinct pathological lesion, not due to preparation for the microscope or to increased activity, and is probably the initial process, followed by atrophy; just as we find weakness the first symptom, followed by atrophy. The changes in the connective tissue, increase of nuclei and slight hyperplasia, followed as the muscular fibres atrophy, by marked hyperplasia and lipomatosis, are secondary. The whole process cannot well be regarded as inflammatory. In spite of the absence of discoverable changes in the nervous system, and the present belief that the trouble is a primary myopathy, Erb is inclined to believe that the muscular changes are due to dynamic, as yet undiscoverable changes in the nerve centres; this opinion is based upon the heredity, the localization of the morbid process in definite muscles and nerve territories, and the coexistence of other nervous troubles, such as epilepsy and idiocy, and the occurrence of similar muscular changes in undoubtedly spinal disease.

THE PATHOLOGY OF FACIAL PARALYSIS.

Minkowski⁴ has had an opportunity to make an autopsy on a patient who was recovering from typical "rheumatic" facial paralysis due to cold, and this autopsy contradicts the current belief that the paralysis is due to an inflammatory swelling of the connective tissue compressing the nerve in the Fallopian canal.

¹ Deutsche Zeitschr. f. Nervenheilk., I., 13, 173, 1891.

² See this Journal, September 16, 1886.

³ Berliner klin. Wochenschr., July 6, 1891.

No changes were found traceable to inflammatory processes in the neurilemma, the nerve was not adherent to the canal, there was no increase of the connective tissue or alteration in the vessels, and the perineurium was normal. From the geniculate ganglion outwards to the periphery the nerve fibres were found in a highly advanced state of degeneration, the degeneration being most marked toward the peripheral extremity of the nerve.

MULTIPLE NEURITIS.

Pal⁴ has recently published a valuable monograph on this subject, giving a review of our knowledge, based on a very extensive bibliography, and a report of eight cases, four of which came to autopsy. In the enumeration of symptoms he notes that the knee-jerks are in rare cases exaggerated, that degenerative reaction may be found in nerves still performing their normal functions, that all forms of sensory disturbance including delayed conduction and double sensations, may be observed, that disturbances of the bladder and rectum and laryngeal and visceral crises may occur, and that the cranial nerves may be involved. His first case presented the picture of a rapidly developing paralysis, involving the ocular muscles, and attended with pain and nerve tenderness. The autopsy, beside peripheral neuritis, showed intense hyperemia of the gray matter of the cord. The second case was of a subacute recurrent type, with paralysis, atrophy, pain on movements, edema, and hyperesthesia. The patient was tubercular and alcoholic. The autopsy showed pulmonary and intestinal tuberculosis, neuritis, and degeneration in Lissauer's tract in the lumbar cord, and in Goll's column in the cervical cord. The third case was also tubercular and alcoholic, with pain, weakness, edema, diminished sensibility, normal electrical reactions, nerve tenderness and loss of reflexes. The autopsy showed neuritis and degeneration of Goll's columns and of the anterior peripheral portion of the anterior columns in the cervical cord. The fourth case was one of chronic lead-poisoning with optic neuritis, eclampsia, colic, paralysis of cranial nerves, ataxia, paresis, loss of knee-jerk and bed-sores. The autopsy showed neuritis, degeneration of the posterior roots and of Burdach's columns, and disseminated degenerations in the lateral and Goll's columns and the cerebellar tract. Pal disbelieves in Erb's hypothesis that neuritis is due to dynamic changes in the ganglion cells, for in his cases, with profound disturbances in the cord, the ganglion cells were intact. Individual portions of almost all the tracts of white matter in the cord were found affected, which renders it probable that the affection involves not only systems of fibres, but may be disseminated, and that the fibres of the conducting tract in the cord may be diseased in the same way as the fibres of the peripheral nerves. In tuberculosis we may find a latent neuritic characterized only by edema and diminution of faradic-cutaneous sensibility.

LANDRY'S PARALYSIS.

The pathology of this affection has recently been much discussed, and much doubt has been expressed as to whether it should be regarded as an independent affection. Ross⁵ collected ninety-three cases, and although he admitted that in some cases no lesion could

be found, he decided that Landry's paralysis was merely an acute form of multiple neuritis. Centanni⁶ found acute interstitial neuritis in a case of Landry's paralysis due, as he thought, to a peculiar bacillus found in the endo-neural lymph spaces of the peripheral nerves. Nauwerck and Barth⁷ report a case where the nerves of the canda equina showed interstitial neuritis to a marked degree, with pronounced disappearance of the nerve fibres. The sciatic nerves and the nerve roots of the cord, especially in the lumbar region, were also involved. They conclude that a typical acute ascending paralysis, with slight sensory symptoms, without implication of the sphincters, and without electrical changes, may prove fatal, and no changes in the central or peripheral nervous system can be discovered. No sure proof has been offered that a typical clinical picture of acute ascending paralysis can be caused by any lesion of the central nervous system; but, if we include in the symptoms severe sensory symptoms, afflictions of the sphincters and electrical changes, such a condition may be caused by disease of the peripheral nerves. Hun⁸ has recently reported a case which seems conclusive. A man of forty-five, gradually began to have stiffness of the legs, and heaviness of the feet. The muscular power and the knee-jerks were diminished. This weakness increased until the legs were wholly paralyzed and the arms began to be affected. Phonation and deglutition were also affected. Examination showed marked disturbance of speech and deglutition, left facial paralysis, great weakness of the arms and absolute paralysis of the legs, loss of reflexes, no muscular tenderness or atrophy, normal sensibility to pain, touch and temperature, normal electrical sensibility. Death followed in a few days from failure of respiration. The brain and cord were normal, few of the larger and smaller veins in the spinal pia mater had their walls infiltrated with round cells, and in some instances the walls were thickened. No hyaline thrombosis, which Kiebs⁹ has regarded as a cause of the disease, was found in the spinal vessels. The anterior roots of the canda equina showed degeneration in about one-tenth of the fibres. The other roots and the peripheral nerves were normal. No bacilli of any sort could be found. There was also a slight meningitis.

MORVAN'S DISEASE.

Charcot¹⁰ has recently called attention to a rare affection first described by Morvan, a Breton physician, in 1883, and called by him, analgesic paresis with panaritium. The characteristic features of the disease are severe pains at the onset; paresis with analgesia, first on one side and then on the other, and panaritium. The paresis is associated with more or less atrophy of the hand and forearm, and analgesia develops later. There is also anesthesia to touch and temperature, and Morvan claimed that the dissociation of sensibility seen in syringo-myelia — anesthesia to pain and temperature and normal sensibility to touch — did not occur in this affection. Morvan¹¹ himself has since studied this point more carefully, finding tactile anesthesia in every case. The affection is not uncommon in Brittany, Morvan having seen twenty cases in a population of 50,000, and it is commoner in

men than in women. The panaritium is severe, leading to necrosis and incurable deformities of the hands. Morvan thinks there may be neuritis, but that that is subordinate to some disturbance in the spinal gray matter, and that there is never any cavity formation in the cord. Déjerine¹² shows that there may be pronounced neuritis in syringo-myelia, giving rise to tactile anesthesia, and that syringo-myelia may rarely present a symptom complex identical with that of Morvan's disease, but as Morvan has seen so many cases in a small district, while syringo-myelia is rare, he inclines to the belief that Morvan's disease is associated with some infectious cause, and is, perhaps, to be classed with the infectious or toxic neuritides. The question of the identity of the two afflictions, Morvan's disease and syringo-myelia, has been much discussed, and an autopsy by Joffroy and Achard¹³ seems to throw some light on the subject, confirming Déjerine's position. A man of thirty had panaritium in both hands, with severe pains at first. Sensibility to touch, pain and temperature were diminished. Motion was impaired, but there was no atrophy. Kyphosis existed. The autopsy showed sclerosis of the posterior columns and a marked syringo-myelia, some muscular atrophy, and degenerative neuritis. The authors do not regard the dissociation of sensory disturbances as necessary symptoms of syringo-myelia, nor do they claim that syringo-myelia exists in every case of Morvan's disease; but it seems fair to assume that there is some lesion, not necessarily a cavity, in the same region of the cord in Morvan's disease as there is in syringo-myelia.

CAISSON DISEASE.

Van Rensselaer,¹⁴ in the Merritt H. Cash prize essay, has written a careful monograph on this subject, based on two cases, one with autopsy, and the recorded autopsies. He finds that the macroscopic lesions consist in congestion or softening of the cord, congestion of the brain, and congestion of the internal organs. Microscopic investigation shows that caisson disease is probably due to a lesion of the cord which attains its greatest intensity in the lower dorsal region, which attacks the white matter rather than the gray, and which is of a degenerative nature, or due to a diffuse parenchymatous myelitis. This degeneration is seen chiefly in the posterior and lateral columns, and the gray matter is usually unaffected; ascending and descending degenerations follow. Caisson disease he regards as due to congestion and malnutrition of the internal organs, especially the cord, and this congestion is due to paralysis of the vessel-walls from previous over-distension, and to a lack of *vis a tergo* of the blood-current, because the blood finds easier passage through the peripheral vessels, which had been partly emptied by the previous pressure. The exciting causes are long-continued pressure, great pressure, rapid removal of pressure, exhaustion and cold during removal of pressure, and possibly evolution of gas if the pressure be very suddenly removed, although he thinks the gaseous theory inadequate to explain the whole condition. The predisposing causes are obesity, old age, heart and kidney diseases, and lowered vitality.

(To be continued.)

A JOURNAL of pathology is about to be published at London, under the charge of Dr. Sims Woodhead.

Reports of Societies.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

CHARLES L. SCUDDEER, M.D., SECRETARY.

REGULAR meeting, Wednesday evening, December 2, 1891, DR. A. T. CABOT in the chair.

DR. GEORGE HAVEN read a paper on

RUPTURE OF THE UTERUS.¹

DR. EDWARD REYNOLDS reported

TWO CASES OF RUPTURED UTERUS TREATED EXPECTANTLY.²

DISCUSSION.

DR. C. M. GREEN reported two cases of ruptured uterus treated without operation — both of which recovered. He said:

The first case was in 1886, in a non-pregnant uterus. The woman had had multiple fibroids of the uterus, the symptoms not being of sufficient gravity to warrant hysterectomy. At that time I do not think much was said about the electrical treatment; at any rate, it was not thought of at the time, and the plan was to dilate the uterus in the hope of finding and removing some simple intra-aural or sub-mucous growth, or to curette, in the hope of limiting the hemorrhage. The patient was taken to a private hospital, and an attempt made to dilate the cervix in order to explore the interior with the finger. The steel dilator was used. During the dilatation I became rather tired and the dilator was temporarily taken in hand by another gentleman, who probably used more force than ought to have been used. At any rate, after beginning to explore the uterus the curette, which I introduced, practically disappeared. Then I took a long sponge holder and seized that with long dressing forceps, and that disappeared, so that there was no question about the fact of ruptured uterus. All further attempts at exploring or curetting were given up. I expected the patient would die then and there. There was a good deal of shock. A light tampon was put in the vagina, she was put to bed, and stimulants were used. She rallied after a time, and the next morning her temperature was a little over a hundred, but fell below a hundred that night, and the morning of the third day it was natural. There was no hemorrhage at the time externally. She went on with normal temperature, but on the fourth and fifth days it was a little subnormal, on the evening of the fifth a little above a hundred, and the next morning normal. On the night of the seventh it was 102.5°, and from that point it gradually fell to normal. She made an entire recovery so far as the rupture went. The treatment was expectant. A report of the case may be found in Vol. XIII of the Transactions of the American Gynecological Society.

The other case was a puerperal rupture in 1888. The woman had a deformed pelvis, probably a small flat pelvis. She had been delivered once already by myself, with high forceps, the head having been engaged, and once before by somebody else. She was seen first by Dr. Edward Reynolds. The head was found high: occiput right posterior with extension: there was a deep laceration of the cervix down to the

¹ See page 82 of the Journal.

² See page 80 of the Journal.

vaginal junction. Dr. Reynolds and I both realized the great danger of internal podalic version, and in consideration of the fact that the family was Roman Catholic, and the child living, and that we did not want to do craniotomy if possible to avoid it, we decided after some considerable trepidation, that we would undertake version and take our chances. As a result, the uterus was ruptured. It was not known that the rupture had occurred until it was sought to remove the placenta, and it was found there was no placenta in the uterus. It was found to have disappeared through a rent in the right wall of the uterus rather low down, and was found among the intestines, and removed through the rent.

I wish to speak briefly in reference to the propriety of laparotomy in such cases. There are three great dangers after rupture — shock, hemorrhage and sepsis. Of course, the septic danger comes later, but if a woman survives the primary shock and primary hemorrhage, if she has one, there is one danger left to her it seems to me, and that is the danger from sepsis. Now, if men are aseptic, that danger ought to be entirely removed. If she has shock, that must be treated, and it seems to me it is rarely necessary for the patient to die from shock. Of course, they do sometimes. In the matter of hemorrhage, if the hemorrhage is severe, the patient may die before anything can be done; but if the hemorrhage is slight, then there is time to make preparation for laparotomy to secure the bleeding points. In this case there was no hemorrhage that could be detected. We concluded there was no internal bleeding. There remained the possibilities of sepsis. The uterus had firmly contracted, the rent closed, and we decided to wait. She had peritonitis, and was treated with opium. I did not think there was sepsis at the time. It seemed like a traumatic peritonitis, localized. At the end of two weeks she was dismissed by the medical student who had the immediate care of the case. At the end of a month she said she was as well as ever. I will simply state the fact that after about two years she had another child, and she insisted on being delivered on the hands and knees so that the student was unable to say what the position of the child was. The child was born without assistance. I got there before the placenta came away, and thought I felt a cicatricial ridge along the right side of the uterus where the tear was. She made a good recovery.

As regards the treatment of obstetrical ruptures of the uterus, I stated in my paper upon this subject my own opinion at that time, and I do not think I have any reason to alter it.

Parvin, in the discussion of the report of my second case, said: "There is no treatment for ruptures of the uterus in childbirth, and the question to be settled is in what cases should the abdomen be opened, and in what simple drainage by the vagina can be relied upon; certainly, the results obtained by the latter in recent years are very encouraging. Probably the solution of the question is this, that where the tear is in such a position that vaginal drainage is perfect, the abdomen need not be opened; but if such drainage is impossible, or imperfect, then section is indicated."

It seems to me that that covers the subject well. If then, as Frommel found in some of his cases, that much detritus has not escaped into the abdominal cavity, if the child has not escaped there either wholly or in large part, and if a large amount of bleeding has not taken place making it necessary to clean out large

quantities of blood-clots and tie the bleeding points, it seems to me much can be expected from the treatment by vaginal drainage. If, on the other hand, as in Dr. Haven's case, or in most of the non-puerperal cases, there is sepsis, as unfortunately there is in many of them, then it seems to me there is nothing to be done but laparotomy, suture of the uterus and thorough flushing of the abdominal cavity; but I feel it is not to be taken as a foregone conclusion that because the uterus is ruptured therefore there must be laparotomy. Such cases will often recover without laparotomy, provided you can have good drainage.

DR. M. H. RICHARDSON: It seems to me that the most important point in both forms of ruptured uterus and in ruptures of abdominal viscera generally, is the matter of sepsis. I have always considered it very difficult to make the utero-vaginal canal perfectly aseptic. The dangers of septic infection are certainly great in abdominal hysterectomies, after the amputation of the uterus, where the uterine canal is exposed. I think the rules that have been laid down by Dr. Reynolds for the treatment of ruptured uterus, are very satisfactory. I do not agree with those who say that there is not considerable danger from shock in laparotomy. In my experience the danger is great in certain cases, proportional, perhaps, to the amount of exhaustion and anemia present from the condition calling for the operation. In regard to drainage, I think that we have a most satisfactory form in vaginal hysterectomy. I saw the case Dr. Strong has reported. In this case there was a septic peritonitis of the fulminating and rapidly fatal variety, which might have been avoided had this woman received the proper drainage and aseptic care in the beginning. This might have been accomplished by the vaginal method. I have had no experience with rupture of the utero-vaginal canal into the abdominal cavity, except in one case where a woman sat down upon a glass syringe and made a hole in the posterior cul-de-sac. She recovered after suture.

In my opinion a general septic peritonitis from whatever cause, is essentially a fatal disease whether you treat it by laparotomy or salines or by any other method. I refer to those cases of rapidly-spreading peritonitis, accompanied by total peristaltic paralysis with continuous and uncontrollable vomiting, and my remarks in this connection apply to those cases in which I have opened the abdominal cavity before or after death, and have found physical evidence of septic general peritonitis. I have yet to see any case of this kind recover under any form of treatment, surgical or medical. In other cases with similar symptoms, where the diagnosis has been unverified either by operation or autopsy, I have met with the same disastrous results whether they have been treated by opium or by salines. I have seen such results in perforations of the stomach and intestines, appendicitis, and after laparotomies. In all there has been the same rapid progress to a fatal end, unchecked by any method of treatment whatsoever.

DR. HAVEN: Dr. Reynolds spoke of statistics regarding ruptures treated by drainage and by laparotomy. He was, I think, particularly fortunate in the cases reported to-night. The statistics of all the cases I could find showed a mortality of about fifty per cent. when treated by drainage; on the contrary, Winckel had fourteen cases of rupture where he did laparotomy and four died. Besides that I have notes of eight cases

with three deaths, in all twenty-two cases with seven deaths, or about sixty-six per cent. of recoveries.

Dr. Reynolds, I understood, would wait to see if hemorrhage occurred after rupture. It seems to me that is a dangerous thing to do. The uterus is an erectile organ, and although it may be firmly contracted at one time, yet in the course of a half-hour or an hour it may be quite large and relaxed, permitting a short hemorrhage to take place. You see this in the uterus after delivery, where it is hard and quite small at one time and a short time later quite relaxed.

As far as the treatment of septic peritonitis is concerned, I fully agree with him that the open treatment is the treatment *par excellence*. I have seen a number of cases among the out-patients of the Lying-in Hospital, and I have never yet seen a case that did not get well under salines and the open treatment, I do not doubt, however, that there are some where this treatment is of no avail.

In regard to Dr. Green's case, I think there is one thing to be considered, namely, the fibroids which were present; disturbing them might have caused a great deal of hemorrhage, only to be controlled by total extirpation of the organ.

As far as the danger from sepsis is concerned, I do not think it is augmented at all by the escape of liquor amnii into the abdominal cavity. In the cases reported in which this occurred it made no difference. The escape of a macerated fetus, on the other hand, was followed in almost every case by death.

One other thing that should be remembered is that the gut may come down through the tear and become gangrenous. This may take place several hours after the tear has occurred, and is one source of danger, which I think has not received due consideration.

I agree with Dr. Strong in regard to the fact that punctured wounds of the uterus do not call for laparotomy. I think such cases should be left entirely to nature.

DR. REYNOLDS: I was a little surprised to hear two or three gentlemen speak of the cavity of the vagina and uterus as necessarily septic. My own experience with it obstetrically and surgically is that the vagina is about as readily cleansed as the abdominal wall. I think the fact that we are accustomed to expect asepsis in vaginal hysterectomy is good evidence of that fact.

In regard to one of Dr. Richardson's remarks, I should feel that in any case in which the drainage was not satisfactory that I should wish to open the abdomen for the treatment of septic peritonitis as soon as I felt that it was getting beyond the control of other means.

In response to Dr. Richardson's statement that he had never seen septic peritonitis, when once general and well underway, influenced by any form of treatment, I should like to speak of the most strongly illustrative case out of a good many that I have seen. I was called two or three years ago to one of the outpatients of the Lying-in Hospital, who had been by misunderstanding, neglected for about forty-eight hours after sepsis commenced. The interior of the uterus was septic, the woman lying on the bed with knees drawn up, abdomen tympanitic and swollen, vomiting constant, temperature 103° or 104° . I thought she was going to die without question. I curedtted the uterus and directed the husband to give her a teaspoonful of Epsom salts in one-half tumblerful

of water every two hours until the bowels moved. I called the next morning and found the woman lying flat in bed, and comfortable, pain gone, vomiting stopped, abdomen flat, etc. The husband said he had given her two teaspoonfuls every hour, and had counted the movements up to twenty, when he stopped.

As regards the statistics given by Dr. Haven, in which only five per cent. recovered without laparotomy, it is my impression that the statistics date back into the pre-aseptic period.

DR. HAVEN: There has been no difference in the statistics in the two periods.

DR. REYNOLDS: As regards the question of waiting to see whether hemorrhage would occur, that is, whether reaction occurred or not, in the four cases I have seen, reaction occurred distinctly, there being no hemorrhage, in fifteen or twenty minutes, and I do not think you would get ready to do laparotomy under an hour.

DR. M. H. RICHARDSON AND DR. J. G. MUMFORD reported a case of

CYST OF THE PANCREAS.³

DR. CUSHING asked whether any cyst fluid escaped into the abdominal cavity and whether there was any drainage.

DR. RICHARDSON: I think some must have escaped, but no considerable quantity. It was impossible entirely to prevent the escape of fluid. This was washed out by a superficial flushing. There was no drainage except of the cyst itself. In both cases the tumor was, to a certain extent, adherent to the transverse colon, so that the fluid did not escape freely into the abdominal cavity. It was impossible to prevent the escape of a small amount, however, but it did not seem to do any harm.

DR. E. W. CUSHING reported a case of
ABDOMINAL AND VAGINAL SECTION FOR UTERINE
TUMOR.⁴

DR. CABOT asked Dr. Cushing how he cleansed his hands after vaginal and before abdominal operation.

DR. CUSHING: With corrosive sublimate.

DR. A. T. CABOT said that during the past summer he had been using peroxide of hydrogen in a fifteen volume solution quite extensively for the cleansing of his hands. He had found it especially useful in those cases where he was obliged to make a vaginal examination, and to follow it at once by a laparotomy. Cultures made from the hand by Dr. A. K. Stone seemed to show that the washing with peroxide of hydrogen added very considerably to the safety. This does not give any more thorough disinfection than washing with permanganate of potash in a saturated solution, and afterwards decolorizing the hands with oxalic acid; it has, however, the great advantage of being the quicker method, as the peroxide does not have any coloring effect on the hands.

Dr. Cabot said that he was glad to hear Dr. Cushing speak of the importance of curetting and cauterizing fungous growths of the cervix in feeble persons, as a preliminary to vaginal hysterectomy, thus giving the patient a chance to pick up strength before the severer operation. He said he had followed this plan in several cases with a good deal of satisfaction, and found that the previous removal of the cervix did not add to the difficulty of the vaginal extirpation of the uterus.

³ See page 86 of the Journal.

⁴ See page 85 of the Journal.

DR. CUSHING: I sometimes use creolin or naphthalin in connection with sublimate.

DR. REYNOLDS: I should like to speak of my experience with creolin. When creolin is used in the vagina it dissolves the vaginal mucous so thoroughly that it leaves the vaginal wall macroscopically clean and accessible to the action of the corrosive, which, if used first, coagulates the mucus and leaves a layer of it over the vaginal wall. I take a gauze sponge soaked in creolin and scrub the vagina with it before an examination is made, and I think it not only saves dirt on the fingers but makes it possible to aseptize the vagina afterwards. It is in itself a good antiseptic.

DR. CUSHING then showed a compound antiseptic powder.

AMERICAN ORTHOPÆDIC ASSOCIATION.

WASHINGTON, SEPTEMBER 23, 1891.

DISCUSSION ON CONGENITAL DISLOCATION OF THE HIP, WITH NEW APPARATUS FOR ITS TREATMENT,¹
by A. M. PHELPS, M.D., of New York.

DR. HENRY LING TAYLOR, of New York, said that there were at least two classes of congenital luxations at the hip, namely, those in which the luxation is produced at the time of labor, and those in which the condition is caused by an arrest of the growth of the acetabulum. He had had a case in which the luxation was unilateral, and in which there was a history of version and forcible delivery by traction on the luxated extremity. About six years ago he had presented to the New York Pathological Society a specimen of congenital dislocation which he had removed from a minute aged man. In this case, not only were the acetabula shallow and narrow, but the entire pelvis was very light, and portions of the bones were as thin as an eggshell. Besides these, there was a fissure of the sacrum, giving additional evidence of the imperfect development of the whole pelvis.

DR. N. M. SHAFFER, of New York, had had two cases of unilateral congenital dislocation in children, which he had treated by the straight traction splint until the maximum amount of lengthening had been obtained, when a modified apparatus with a joint at the knee and a perineal support was employed. The best result had been obtained in a case which he had seen with Dr. Saads, and in which an attempt was made, under ether, to reduce the dislocation. After using considerable force this plan of reduction was found not to be feasible, but the manipulation produced, so to speak, an adhesive inflammation which was beneficial, and at the end of two years there was only about half an inch of shortening and a very firm joint.

DR. CHARLES C. FOSTER, of Cambridge, said that the best recorded result had been obtained in the case treated by Dr. Brown. He had assisted in the treatment of that case, and could speak very positively of the great amount of faithful, patient work which had been required to bring about this result. The child belonged to a family a number of whose members had loose joints. The femur could be rubbed all over the pelvis, and there was an acetabulum so slight as to be almost inappreciable. The child was put to bed, and pressure applied to keep the bone in the

acetabulum, and then by an arrangement of straps the limb was exercised in this position several times every day. As soon as there was evidence of deepening of the acetabulum, these exercises were modified. No splint was used at any time, but when the child was removed from bed it was placed in a sort of go-cart, supported on a saddle, so that it could be allowed very gradually to bear more and more weight upon the foot.

DR. SAMUEL KETCH, of New York, said that about two years ago, he reported in Keating's *Encyclopaedia of the Diseases of Children*, about fifty-six cases of congenital dislocation of various joints, discussing in succession the bearing upon this condition of heredity, parturition, location and treatment. Heredity did not appear to be an etiological factor. The vast majority of labors in these cases were absolutely normal, showing the fallacy of the old idea advocated by Mr. Brodhurst concerning parturition as a cause. In this collection of cases there were no anterior dislocations. He had been unable to determine whether these cases were examples of simple malformation or of lack of development. One case was very remarkable, inasmuch as it was an instance of congenital dislocation of almost every joint in the body. In this boy there were decided evidence of rickets. Regarding mechanical treatment, he was of the opinion that our chief aim should be to improve the gait, and secure a new position for the head of the bone giving greater length to the extremity. An ordinary long traction splint with the addition of a pad and surcingle to hold the head of the bone in position, will prove satisfactory in most cases.

DR. ALBERT HOFFA, of Würzburg, said that the best that could be obtained by mechanical treatment was to pull down the head of the femur, and so improve the patient's gait. He thought the best results would be obtained by operation. The chief impediment to reduction is the shortening of the muscles running from the pelvis to the leg, owing to the trochanter major being nearer to the iliac crest than in the normal subject. The posterior leg muscles are also shortened. The reduction in adult cases is so difficult, that he would not advise attempting operative reduction in patients over eight or ten years of age. In children of from three to six years, the reduction is very easy. After cutting off the joint and separating all the soft parts from the upper end of the femur, it is very easy to pull down the femoral head until it is in the position of the old acetabulum. It is desirable next to enlarge this acetabulum. It has been said that it is impossible to do this, but by reference to the specimen exhibited by Dr. Phelps, it will be seen that the acetabulum is the thickest part of the pelvis, and there is no difficulty whatever in making a sufficiently deep acetabulum. In his first operations he used a periosteal flap which he sewed over the trochanter major, but subsequently he found that it was not necessary to make this flap, for, if the cavity be sufficiently deep, there is no danger of the head of the bone coming down. The chief feature of his operation consisted in saving the head, and thereby obtaining a healthy joint. His first operations were performed about two years ago, and about two months since he examined the first case and found a perfectly movable joint and the absence of the awkward gait characteristic of congenital dislocation. Even lordosis was absent. In all of his cases he had found a rudi-

¹ See page 77 of the Journal.

mentary acetabulum, which was triangular in shape. Some cases had been reported in France in which the site of the acetabulum was occupied by an exostosis, but no such condition had existed in any of his cases.

DR. HOWARD MARSH, of England, called attention to the statement which had been made concerning the absence of any causal relation between these dislocations and heredity. He did not consider that this remark correctly represented the subject, for, many years ago, he had had a case of congenital dislocation of the hip brought to him whose mother also had the same condition with very free telescopic movement on the pelvic wall. The condition found in the child was exactly similar to that shown in the specimen just presented. The anterior position is the most favorable one because in these cases there is no lordosis, for the lordosis depends upon the extent to which the femur is displaced backward upon the walls of the pelvis. Congenital dislocations should be divided into (1) those in which the bone slips about on the walls of the pelvis, and (2) those in which it is fixed. In the majority of cases it is so fixed, and under these circumstances he did not think operative measures should be undertaken. Such measures were more properly applicable to cases where the head of the femur is high up and movable.

DR. JOHN RIDLOW, of New York, had had an opportunity of seeing one of Dr. Phelps's cases. He had also had two cases of this condition in his own practice, and he desired to direct attention to the uselessness of mechanical treatment. Dr. Brown's case was a posterior one, and the result was good, and this was what might be expected. In his own first case, after the use of traction by the Taylor splint in bed for a year, until the shortening had been reduced, on placing the head of the bone over the acetabulum the entire limb was rotated inwards about ninety degrees. In the process of growth from birth to the age of eleven years, a distortion of the neck had occurred, and, therefore, simply replacing the bone only resulted in placing the feet at right angles—a worse condition than at the beginning. In these cases mechanical treatment is obviously of no benefit. He thought anterior dislocations more hopeless than posterior ones under mechanical treatment.

DR. R. H. SAYRE, of New York, had had a case of dislocation on the dorsum of the ilium. Here he had brought down the head on to the acetabulum, but it now had a tendency to become a pubic dislocation. He uses an instrument similar to the long traction splint, but with a joint at the pelvis, so that the head can, if desired, make movements at the hip-joint with the idea of assisting in creating a new acetabulum. He thought with Dr. Foster, that a grinding motion is an important factor in securing such a result, provided the head of the bone could be retained in the proper position. The iron ring in Dr. Phelps's apparatus he did not think would prove as good in practice as a strap, which could be removed from time to time. The cases in which the bone remained in a fixed position were best left alone.

DR. E. H. BRADFORD, of Boston, referred to a case which he had reported on a previous occasion, in which he had been using a very light portable splint, which he desired to exhibit to the Association.

DR. DE FOREST WILLARD, of Philadelphia, considered the movable cases the most hopeful ones for operation. In cases where there is slight movement,

it is better to combine operative and mechanical treatment, beginning first with rather forcible attempts at reduction, in order to produce inflammation, and then making continuous horizontal traction, as well as employing systematic exercises with the idea of exciting sufficient inflammation to hold it in place. Lastly came the use of a retaining splint.

DR. L. A. WEIGEL, of Rochester, during the past two years had seen three cases of congenital misplacement, two of them being unilateral, and in all of them, by simple traction upon the leg, the limb could be brought down to the normal length, and there was a perceptible play on striking the rudimentary acetabulum. In some cases the muscles on the affected side were rather imperfectly developed. He did not think that in old cases the shortening could be overcome.

DR. PHELPS, in closing the discussion, said, regarding the etiology, he had traced cases and had found that heredity appeared to play an important part. After his splint has been worn for a year the upper part of it is removed to allow of motion, and the patient walks upon it, discarding the crutches. The vast majority of the cases he believed were really dislocations *in utero* or at birth, with subsequent non-development of the acetabulum, and not congenital non-development of the acetabulum allowing of misplacement of the head of the femur, as has been taught and still is believed by a large portion of the profession. The pathological specimen presented appeared to confirm that idea.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

FOURTH Annual Meeting, held in Richmond, Va., November 10, 11 and 12, 1891.

FIRST DAY.—MORNING SESSION.

The Association convened in the hall of the Young Men's Christian Association, and was called to order by the President, DR. L. S. McMURTRY, of Louisville, Ky., at 10 A. M. Prayer was offered by the Rev. D. M. Hooge.

The first paper read was by DR. J. W. LONG, of Randleman, N. C., entitled,

ALBUMINURIA; ITS RELATION TO SURGICAL OPERATIONS.

He drew the following conclusions:

Neither ether nor chloroform injures healthy kidneys, as a rule. When renal disturbances from the use of an anesthetic, the kidneys being healthy, do occur, they are due rather to prolonged narcosis, exposure of the patient, or perhaps to the combined influences of the operation and the anesthetic. A mild degree of albuminuria or nephritis, especially if recent, is not a contraindication to the use of chloroform or ether. Even in the presence of advanced and extensive renal changes, an anesthetic may be employed, provided the patient or family are advised of the additional risk. Of the two anesthetics usually employed, it is yet a mooted question as to which is the safer so far as the kidneys are concerned, unless it be in obstetrical operations. While it is by no means the rule, profound functional disturbances and even organic lesions may be induced by an operation, apart from the influence of the anesthetic. Such renal changes are due to reflex sympathetic action of sepsis, or both.

Operations in certain regions, notably the abdominal, genito-urinary, about the mouth and rectum, are specially liable to produce renal complications. A healthy condition of the kidneys, minimizes, but does not obviate, the danger referred to. Albuminuria is always indicative of renal lesions, and should be regarded with distrust; but it is not positive contraindication to an operation. When albuminuria is associated with other evidences of advanced renal changes, no operation should be undertaken without first candidly stating to the patient, or friends, the dangers incident to the condition of the kidneys. Paradoxical as it may seem, an operation will sometimes relieve an albuminuria due to acute affections. No surgeon is justified in undertaking an operation without first knowing the state of his patient's kidneys.

FIRST DAY.—AFTERNOON SESSION.

DR. JOSEPH PRICE, of Philadelphia, Pa., read a paper on

COMPLICATIONS IN PELVIC SURGERY, AND HOW TO DEAL WITH THEM.

The author's reasons for choosing this subject were that the importance of recognizing the part that complications play in the work of the surgeon, are not appreciated by the generality of medical men, by general surgeons, and least of all, by the tyro in surgery, and by those who are anxious to begin their surgical investigations and trial-trips by an entrance into the domain of abdominal or pelvic surgery. The complications in this special branch of surgery are primarily those of surgery in general, with many things superadded to render them formidable. It may be the intention of the surgeon to remove the appendages for a bleeding fibroid. In ordinary operations the removal of the uterine appendages is to the skilled abdominal or pelvic surgeon one of the simplest of undertakings. If, however, he attempts to accomplish their removal, without holding in mind the complications that, as a rule, exist, or if he is a neophyte or an experimental dabbler, he will find too late in many cases, that he has attempted an operation that he cannot finish, or if he does complete it, he has also sacrificed his patient, or rendered her worse off than before. In other words, to accomplish a cure, he must abandon removal of the appendages and perform hysterectomy, which has but little in common with the operation originally proposed. If this idea is still further carried out, we shall find that complications do not confine themselves to one system of organs, but extend to all surrounding structures by reason of inflammatory adhesions. This is true of the bladder, ureters, intestine, omentum, stomach and liver. Adhesions are the bane of abdominal and pelvic surgery, and hence we see that the greatest mistakes and failures are made by those who, from a knowledge of abdominal surgery simply, have attempted to deal with pelvic inflammations. The abdominal surgeons who can be counted as really successful pelvic surgeons are therefore few. This is said with no intention of detracting from the importance of abdominal surgery. The strictly abdominal organs must always enter largely into the domain of surgery.

With regard to irrigation, we must get out of our heads the idea that it is dangerous. Very often in the writer's experience has hot water brought about a speedy reaction in patients whose lives were almost despaired of. We are told that cases do not need

flushing, that they do badly under it. Dr. Price believes that they do need flushing if they are desperate cases, and if they do badly they do so, not on account of the flushing, but because of the operation that preceded it. Next, we have a resort in packing. Gauze packing accurately applied to the bleeding or oozing surfaces, so that it can be removed without interfering with the otherwise completed operation, is of infinite value in hemorrhage. It can be suffered to remain indefinitely almost, broadly speaking; at least, up to sixty or seventy hours, if absolutely clean and fresh, either salicylated or iodoformized. The drainage tube controls hemorrhage. The drainage-tube is currently spoken of as if it were an annex to pelvic surgery, easily dispensed with. The writer uses it almost without exception in adhesions. His results are better than those obtained without its use.

The plea of the paper was for absolutely exact, painstaking work that shall leave nothing for regret, nothing to do over, nothing to explain, but shall stand out in the light of results as justifiable, scientific and perfect when put beside methods that palliate without curing, and are no more a part of real surgery than is hypnotism refreshing sleep.

DR. CORNELIUS KOLLOCK, of Cheraw, S. C., read a paper entitled,

OVARIAN CYSTS, WITH THE REPORT OF A CASE OF OVARIOTOMY IN A YOUNG GIRL.

He said the causes of ovarian cyst seemed to be still a question *sub judice* in the minds of those who are the most progressive and who have made the greatest advancement in the science of gynecology. Various theories have been put forth by those of larger experience, who are earnest seekers after truth, and who are patient investigators of all unnatural and morbid phenomena. But no satisfactory decision has been obtained from all the patient and searching investigation that has been made as to the cause of this singular, unaccountable and sometimes fatal neoplasm, characterized by histological diversity from the viscera of which it is a production. Some of the theories seemed, at a glance, to be plausible, but upon close study we find they will not bear inspection.

Miss C. L. H., was eleven years, eight months, and nineteen days old; general health perfect in every particular. Menstruation first appeared about two months before she was eleven years of age, and continued with perfect regularity, never excessive or scant, nor was it accompanied by the slightest pain. Her physique was fine in every way. Though less than twelve years of age, she weighed 135 pounds; was strong and active. Her breasts are full and large as those of a woman at thirty-five. She was very handsome, had a fine voice and sang beautifully. She was very intellectual, and stood at the head in all her classes in a large high school. I saw her for the first time on the 9th of January, 1891. The abdomen was greatly distended, but facies ovariana was not very pronounced. I was confident she had an ovarian cyst, and I rather suspected she had two. On the 6th of January I made a section about three inches below the umbilicus, and removed a cyst from each side, the one on the left weighing twelve pounds, and that on the right seven pounds. A more prompt and complete recovery the writer had never seen from the simplest operation. Union by first intention took place, and the sutures (silver wire) were removed at the end of the seventh

day. In twelve days she was up and about her room, and on the twenty-third day after the operation returned to her home, a distance of 200 miles.

It is now ten months since double ovariotomy was done on this young girl, and there has not been the slightest discharge from her of any kind. At each menstrual period, there was considerable commotion in the pelvic region, attended with some uneasiness in the head and back; but at each period these symptoms decreased, and the last two were accompanied by no pain whatever. The remarkable physical development in this case still continues. It is now ten months since the operation. She has gained six pounds in weight, weighing 141 pounds, and looks better than before she underwent ovariotomy. This young girl came from the purest and healthiest stock of people in this region. Not an individual on either side was ever known to have any constitutional trouble of any kind. Her mother and family physician say they never knew her to be the least indisposed in any way.

SECOND DAY.

DR. WILLIAM WARREN POTTER, of Buffalo, N. Y., read a paper entitled,

A MEDICO-LEGAL ASPECT TO PELVIC INFLAMMATION, in which he said that pelvic inflammations in women have been described, discussed and debated from almost every point of view imaginable, until our periodical medical literature is flooded with articles on the subject, and medical society transactions are teeming and bristling with papers pertaining thereto. So far, however, he had not observed that any one had undertaken to discuss these intra-pelvic conditions from a medico-legal standpoint. It was his purpose to present that aspect of the question, taking for his text a case that developed an interesting problem in that respect.

After giving a history of the case, Dr. Potter emphasized the following points:

(1) The intimate anatomical relations between the pelvic organs and the larger joints of the lower extremities, especially the hip and knee joints; render them liable to reflexes.

(2) The importance of careful diagnosis at the outset lest grave errors, and possible disastrous consequences may result from treatment.

(3) The medico-legal bearing that errors of judgment in diagnosis and treatment may have in relation to the patient, as well as upon the reputation of the physician.

THE MEDICO-LEGAL ASPECT OF INTESTINAL SURGERY.

DR. JOHN D. S. DAVIS, of Birmingham, Ala., read a paper on this subject. He said many physicians and surgeons who condemn all mechanical aids for intestinal repair, know not how to use them; never saw them used; refuse to endorse a resection for gunshot or stab wounds; have been known to go in the witness-box for purposes of condemnation and disapproval when they knew no more about intestinal surgery than a wild Indian about school-teaching.

In this day of specialties in medicine, but few general surgeons have either the appreciation, opportunity or disposition to qualify themselves as expert operators in intestinal surgery; but many — to the discredit of the profession — voluntarily appear in the criminal courts of the country pretending to be such, wise and proficient. One of the greatest professional sins of the day is perverted knowledge of concealed ignorance.

It is too often that physicians and surgeons weaken and invalidate their opinions to a greater or less degree by unscrupulous interest in behalf of those employing them, a fact cunningly turned to advantage for defendants in criminal prosecution, and for like reason may become dangerous to the operators they oppose and envy. To be able to do a laparotomy for stab or gunshot wounds of the intestines, inflicted by one with murderous intent and be able to evade civil and criminal liability, the operator must be able to show evidence of ordinary surgical knowledge in the requirement of the special operation to be performed; he must possess ordinary surgical ability for doing the special operation to be performed; he must exercise ordinary prudence in performing the special operation to be done, as to time, place, antiseptics, asepsis, assistance, nurses, and after-treatment; he must perform the special operation in an ordinary skilful manner. Hence, to prevent confusion, it will be well, if possible, to determine what constitutes ordinary surgical knowledge, ability, prudence and skill. Upon these depend the whole medico-legal status of the intestinal surgeon, and upon which the expert should be required to depend also. According to the practices and rulings of courts in this country, the word ordinary, in its surgical adjectiveness, means that the surgeon shall be capable of and exercise that surgical knowledge, ability, prudence, and skill with which a fair proportion of the surgeons of his given locality are endowed, and not that of the highest lights of his profession.

The President, DR. L. S. McMURTRY, of Louisville, Ky., delivered the annual address, taking for his subject

A PLEA FOR PROGRESSIVE SURGERY.

He said within fifteen years the entire practice of surgery has been revolutionized. New methods have been introduced and new regions invaded. Comparatively recent teachings have become obsolete in practice and modern treatises recast. The science and art of gynecology, which a few years since was limited to a small and narrow field, has grown into a great branch of medical science and practice. Formerly divided between midwifery and surgery, as a minor branch of one or both, gynecology has become an independent and essential department of the healing art.

When Marion Sims announced, through the columns of the *British Medical Journal*, that he believed the proper course of treatment in every case of gunshot wound of the abdomen is to open the abdomen, search for the bleeding points and secure them, and suture intestinal perforations, he was pronounced by many eminent surgeons to be a dreamer. The suggestion of Sims was most timely, and shortly afterwards Bull successfully executed the operation. For years the treatment of opium in full doses had been pursued, with death in waiting. Now there is scarcely a State in the Union in which one or more patients have not been rescued from certain death by prompt resort to operative treatment. He mentioned these circumstances to illustrate and emphasize the point that surgery is advanced more by the aggressiveness of the surgeon than by timidity. In the face of desperate conditions of disease and injury, where there can be no safety whatever in delay and palliation, the only treatment worthy of consideration is the aggressive course which promises success. Under such conditions the most heroic surgery is conservative, and any other course is not conservative.

DR. JOSEPH TABER JOHNSON, of Washington, D. C., followed with a paper on

THE GROWTH OF FIBROID TUMORS OF THE UTERUS AFTER THE MENOPAUSE.

He said the object of the paper was to put on record cases and opinions in opposition to a common view of this important subject, and to aid in recasting our views and in modifying our practice.

He had within the past five years seen at least a dozen women with large growing and troublesome fibroid tumors of the uterus, who were over fifty years of age; some of them over sixty. These women had been assured by their physicians, that, if they could get along somehow until after the change of life, their tumors would not only stop growing, but they would lessen in size, and probably go away altogether; at least, the troublesome and dangerous symptoms would disappear. They had been advised against any radical operation, and encouraged to believe that as they grew older, they would get entirely well. In perhaps the majority of cases this might prove to be very good advice; but the point which the author wishes to make is that as we are now better acquainted with the history and behavior of these tumors, that this is no longer safe advice to give. We cannot assure any woman that her tumor may not prove to be one of the exceptional cases, and that it may not grow more rapidly after the menopause than it did before, or that it may not present complications equally distressing and disastrous. When from forty to fifty per cent. of women subjected to supra-vaginal hysterectomy died from the effects of the operation, this was very safe and conservative counsel to follow. The possible dangers of the tumor were not equal to the probable dangers of the operation.

The "rule" stated in the text-books that uterine fibromata cease to grow after the menopause, has many more exceptions than is generally supposed. When they continue to grow after the menopause, they pursue a more disastrous course than before. They more frequently become cystic, calcareous or have abscesses develop in them. These conditions, requiring operation according to well-known rules of surgery, the patients are in a less favorable condition for recovery than before the menopause. If the above conclusions are admitted to be true, it must follow that they furnish additional indications for more frequent and early resort to the radical operation. In the hands of the best operators in cases where a pedicle can be secured, the mortality of supra-vaginal hysterectomy is rapidly approaching that of ovariotomy.

DR. C. A. L. REED, of Cincinnati, O., read a paper on

THE SURGICAL TREATMENT OF ANTERIOR DISPLACEMENTS OF THE UTERUS.

Anterior displacements of the uterus, when they exist to the pathological degree, are the opprobria of gynecology. It is indeed true that many wombs lean far forward without inducing symptoms, but it is likewise true that many of them that are thus malposed do entail symptoms, objective and subjective, that frequently baffle our resources. It is a misfortune, too, that many of all the displacements to which the womb is liable, those in which the organ deviates anteriorly to the normal axis, are vastly the more prevalent. Thus, in an aggregate of 494 cases by Nonat, Meadows, Scan-

zoni, Valleix and Hewitt, quoted by Thomas and Mundé, there were 294 ante-flexions, and 180 retro-flexions; while Mundé himself reports 294 ante-flexions, 33 retro-flexions and 10 latero-flexions in a total of 337 cases. As the latter authority is disposed to look upon ante-flexions in their minor stages as a physiological (even congenital) condition, it is legitimate to infer that his statistics are based upon observations of displacements in the pathological degree. The conclusion is forced upon us, then, that of all the displacements of the uterus, those of the anterior variety are more frequent; while the records of practice will force us, likewise, to the conclusion that of all the womb displacements those of the anterior variety are less amenable to treatment than are any of the others.

In the treatment, the term *surgical* is employed in contradistinction to any method of treatment by pessaries, tamponnade or electricity. It may be premised that all surgical methods devised for the relief of these conditions should be directed, first, to the removal, when practicable, of the causes of the diseased conditions proper, and finally, to the readjustment of the diseased organs to the normal physical forces of the pelvis.

In conclusion, the author desired the Association to consider:

- (1) The etiological relationship of contracture of the utero-sacral ligaments to ante-fexion.
- (2) The possibility of overcoming this condition by such conservative measures as rest, pelvic depletion and appropriate manipulations.
- (3) The feasibility of removing the obstructive dysmenorrhea and the sterility usually incident to these cases by the plastic operation which he had described.
- (4) The inexpediency of forcible dilatation for the relief of these cases, and its inability to effect a permanent cure.

THE PART THE SHOULDERS PLAY IN PRODUCING LACERATION OF THE PERINEUM, WITH SUGGESTIONS FOR ITS PREVENTION.

This was the title of a paper read by DR. W. D. HAGGARD, of Nashville, Tennessee, in which he made the following suggestions:

The patient should occupy the left lateral decubitus, at least during the second stage of labor. Overcome the rigidity of the vulvar outlet by the judicious use of chloroform. The presenting part of the child should be supported and not the perineum, during the passage of the head and shoulders. Support the head by pressing it well up under the symphysis pubis, by placing the right thumb in the rectum and fingers of right hand extended over the occiput. To retard the exit of the shoulders, pressure should be applied to the trunk and shoulder by placing the index and middle finger of the left hand in the rectum, with the thumb in the vagina to restrain its exit. Support the head and neck by pressure well over the symphysis pubis.

(To be continued.)

A PHARMACEUTICAL CONGRESS. — The World's Congress Auxiliary has issued the prospectus of a pharmaceutical congress, in which it invites all pharmaceutical societies and workers throughout the world to participate, to be held in Chicago, in May or June, 1893. It is suggested that the regular meetings of all pharmaceutical associations and societies be held in connection with this congress.

Recent Literature.

A Clinical Text-Book of Medical Diagnosis for Physicians and Students, Based on the Most Recent Methods of Examination. By OSWALD VIERORDT, M.D., Professor of Medicine at the University of Heidelberg. Authorized Translation, from the Second Improved and Enlarged German Edition, with Additions, by FRANCIS H. STUART, A.M., M.D. With one hundred and seventy-eight illustrations. Philadelphia: W. B. Saunders. 1891.

This book, the first German edition of which was published in 1888, was undertaken by the author as the result of the experience of more than four years of work as teacher of diagnosis in the medical clinic at the University of Leipsic.

The second edition gives the latest methods for examination of the contents of the stomach and of the organs of sense. In teaching the use of instruments and methods of precision, the author, we are glad to note, does not omit to urge the importance of the simple use of the senses, and of individualizing each case.

The book is an excellent one, and fills well a place hitherto unoccupied among medical publications in English. The translator's and the publisher's work is well done.

Zeitschrift für Orthopädische Chirurgie. Stuttgart: Ferdinand Enke.

In welcoming a new magazine, it is customary to state, by way of introduction, the need of such a publication; and in fact there have been but few journals devoted exclusively to orthopedic surgery, and this, we think, is the first to appear in Germany. Under the able editorship of Dr. Albert Hoffa, of Würzburg, it is to be expected that this magazine will have a brilliant future, and certainly, if we can judge from the opening number, it will fill a useful place. It begins with an article by Lorenz on the treatment of lateral curvature, which is both original and of value. This is followed by several articles of interest, among them, one by Hoffa, describing new and original means of correction of deformity of rotation in lateral curvature. For details the reader will have to be referred to the article itself.

In the introductory notice of the editor as a preface to his journal, Dr. Hoffa frankly states his opinion in regard to the position of orthopedic surgery as a specialty; a subject which, as is the case with all new specialties, has given rise to some discussion. He is quite positive in the belief that orthopedic surgery, if restricted entirely to mechanical appliances, will not be destined to a brilliant future, and, in fact, is bound to degenerate, as it has hitherto done in the hands of previous orthopedic surgeons of the past generation who limited themselves to a narrow interpretation of their specialties. In fact, Hoffa is of the opinion that orthopedic surgery would not exist if it were not for the impulse given to it by Delpech, who first added to it operative measures of tenotomy. At the present time when this specialty has been reinforced by new operative procedures which require special skill and experience, the branch deserves renewed attention; but attention should be paid by those who are thoroughly schooled surgeons before they have devoted themselves to a special branch. The magazine is one which, if it maintains the standard of its first number, will be of great service in the medical world.

THE BOSTON

MEDICAL AND SURGICAL JOURNAL.

THURSDAY, JANUARY 28, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Rentances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE NERVOUS AND MENTAL PHENOMENA AND SEQUELAE OF INFLUENZA.

It has long been recognized that the poison of influenza in a large class of cases manifests its effects upon the patient especially by its influence upon the nervous system. Whether the cardio-pulmonary and digestive disturbances are due directly to functional or more serious derangements of the pneumogastric and vasomotor systems, whether cerebro-spinal meningitis, for instance, is simply a malignant form of influenza, is a fair subject for speculation; but that there is a class of cases in which the primary and secondary effects of the poison are felt by the nervous system, as manifested by pain and sensitiveness in various parts, by headache, and by disturbances of cerebration, there can be no doubt.

Dr. Charles K. Mills, of Philadelphia, has brought up the subject in a recent paper before the Philadelphia County Medical Society.¹ He bases his consideration of it upon the broad ground, that all diseases of infectious or toxic origin — epidemic, endemic, sporadic or accidental — may strike any or all parts of the nervous system with a result which will be proportionate: first, to the virulence of the infecting agent; and, second, to the resistance of the individual, whether this is due to constitutional predisposition or to the result of previous injury or disease. The microbes may differ, but a bond of union and close resemblance can be recognized between the effects on the nervous system of all contagious and infectious diseases.

In all these affections at the time of acute onset, if the illness is of a serious character, such symptoms are present as great mental and nervous debility, irritability, restlessness, sleeplessness, or the opposite states of torpor, stupor, hebetude, or coma; delirium; vertigo or syncope; headache, browache, napeache, backache and limbache; pains of all degrees of severity referred to various nerve areas; hyperesthesia of the skin, of muscle-masses, or confined to nerve-trunks or branches; spasms, local or general, and with or without

¹ January 13, 1892.

out unconsciousness; sometimes mental disturbance amounting to true mania or melancholia. During the progress of such affections any one or several of these enumerated symptoms may be present. Supra-orbital pain, for example, may be the only prominent nervous symptom in a case of influenza; headache and back-ache in diphtheria; hyperesthesia in mumps, diabetes, or gout; and mania in a case of puerperal infection. Any infectious or toxic disease may, in brief, produce the same symptom, syndrome, or train of phenomena; and — which is the main point — for the same reason, namely, because of the introduction into the system of an agent which directly and powerfully poisons nervous centres, and possibly also nervous conducting tissues.

Following all infectious, diathetic, or toxic diseases, moreover, or directly springing from them, common experience teaches that we may have great nervous or general weakness; forms of insanity of the depressive type; paresis and paralysis of every grade from an affection of a single muscle to that of all the extremities, and even more; localized spasm or cramp; general convulsions; pains in the nerves, muscles, and joints; and losses or perversions of sensation.

These symptoms and conditions, which may occur at the onset, during or after the subsidence of any infectious or toxic disease, are those which constitute the nervous features of the prevailing epidemic.

Dr. Mills then asks: How is the nervous system affected by influenza? What are its primary or direct effects on the nervous system, and what are some of the more persistent and permanent impairments, and how are these determined by the disease? What are its acute nervous and mental phenomena, and what are the most common sequences? What is the probable pathology of these states, and what treatment is best in view of the neurotic characteristics of the affection?

Acknowledging the great difficulties attending any attempt to classify the nervous and mental phenomena of influenza, he recognizes, firstly, symptoms and conditions which, although manifested in non-nervous organs, are directly traceable to a nervous origin; secondly, affections which would be recognized by all as properly referred to the nervous system; and thirdly, affections occurring in nervous tissues and organs, although, strictly speaking, not nervous diseases.

Without stopping to discuss the possible nervous origin of the fever of influenza, or to explain the catarrh, indigestion, etc., on some neurotic theory, as leading him too far from his immediate subject, the author emphasizes the fact that some of the most prominent pulmonary, cardiac, and vascular affections of influenza can best be explained on neural theories, and inclines to the conclusion, which has been previously advocated by Graves and others, that the pneumonias of influenza are often due to vasomotor paralysis, that they are, in fact, forms of blood stasis or passive congestion from vasomotor paralysis, which in its turn is dependent upon the action of the infection upon the pneumogastric centres and the nervous sys-

tem in general. Many disorders in various parts of the body are, he thinks, best explained on this theory of local vasomotor paralysis.

The peculiar forms of pulse, and the uncertain or perverted action of the heart, extending in some cases to cardiac palsy and death, are in a strict sense nervous phenomena due to paralysis, partial or complete, of the inhibitory apparatus of the heart.

Of those symptoms and affections which would clearly be recognized as belonging to the nervous system, great nervous and mental prostration, both as an acute manifestation and as a persisting sequel, has engaged the attention and required the treatment of all practitioners. The mental depression often present as an initial symptom has been, in some cases, simply overpowering. Some of the patients are affected like individuals whose mental and motor centres have been poisoned to the limits of human endurance, while still permitting the retention of consciousness. In other cases even consciousness itself has been overwhelmed.

Dr. Mills finds that not a few patients who suffered from attacks of influenza during the early period of the present epidemic are still victims of profound neurasthenia, and this in cases which are not distinctively of the melancholic type. These neurasthenics are unable to endure a fair amount of work; their nervous forces are soon routed; they are weak, worrisome and uncuperative. The cardiac weakness which has been left is undoubtedly, he thinks, in part the cause of this neurasthenia.

Among organic nervous diseases which have developed during the influenza or have been left in its wake, are in the order of their frequency, so far as Dr. Mills's personal observation has gone, neuritis, meningitis, myelitis and cerebritis, or various combinations of these inflammatory affections, as, for example, concurrent neuritis and myelitis, meningo-myelitis, or meningo-encephalitis.

He thinks that probably no single affection of the nervous system has been so common during and after influenza and particularly as a sequel of the disorder, as neuritis. Almost every variety of neuritis as regards location and diffusion has been recorded. Multiple neuritis, while not common, has not been rare. Isolated neuritis of almost every cranial nerve has been recorded, with such resulting conditions as optic atrophy, loss of smell and of taste, ophthalmoplegias, both internal and external; oculo-motor, facial, and bulbar or pseudo-bulbar palsies of various types, including true pneumogastric paralysis. Of the forms of local neuritis most common the supra-orbital, intercostal, sciatic and plantar might be mentioned.

The articular pain and other so-called rheumatic manifestations so numerous during and after attacks of influenza are after all best explained on the theory of infectious neuritis or myositis.

Those cases with articular and other pains, and with swelling, recall, in some respects, the endemic or epidemic form of multiple neuritis known as beri-beri.

The neuralgias and neuritis should be distinguished.

Practically those cases should be regarded as neuralgic, in which pain is referred to certain nerve lines or radiations; but in which pain on pressure, and the other phenomena of neuritis, such as anesthesia, vasomotor, and trophic disorders and even paralysis, are absent.

Of diseases of the spinal cord proper, occurring as complications or consequences of influenza, the reported cases are important but not numerous. A few cases of myelitis have been put on record by native and foreign observers — one is cited by Dr. Mills in which all four extremities were paralyzed.

That meningitis, either cerebral, spinal or cerebro-spinal, occurs during the decline of the influenza, cannot be doubted in the light of the evidence which has been presented by various observers, and particularly during the epidemic of the last three years. It is, however, according to the writer, a comparatively rare concomitant or complication.

The reports of cases terminating fatally because of meningitis, must be received cautiously and sometimes incredulously. The form of meningitis most likely to be present in influenza is inflammation of the pia-arachnoid or soft membranes, now often designated lepto-meningitis. This affection *may* exist without pain. A genuine meningitis, sometimes of malignant type, may appear, however, during the progress or closely following influenza.

With reference to the relation between influenza and the psychoses, Dr. Mills quotes and endorses the following conclusions reached by Dr. Leledy:

- (1) Influenza, like other febrile affections, may establish a psychopathy.
- (2) Insanity may develop at various periods of the attack.
- (3) Influenza may induce any form of insanity.
- (4) No specific symptoms are manifested.
- (5) The rôle of influenza in the causation of insanity is a variable one.
- (6) Influenza may be a predisposing or exciting cause.
- (7) In all cases there is some acquired or inherited predisposition.
- (8) The insanity is the result of altered brain nutrition, possibly toxic.
- (9) The onset of the insanity is often sudden, and bears no relation to the severity of the attack of influenza.
- (10) The curability depends on general rather than on special conditions.
- (11) The insane are less disposed to influenza than are the sane.
- (12) In rare instances influenza has cured psychoses.
- (13) The insane may have mental remission during the influenza.
- (14) There is no special indication in treatment.
- (15) Influenza may lead to crimes and to medicico-legal issues.

A delusional melancholia is the most frequent type, and this sometimes assumes the form of melancholia agitata.

In each year in Cook County, Illinois, the epidemic of influenza has been attended by an increase in the number of proceedings for the commitment of the insane, which Church believes cannot be explained by increase or movement of the population of the county.

The use in influenza of hypnotics, narcotics, sedatives and motor depressants, Dr. Mills regards as a question of particular interest in connection with the study of the nervous and mental phenomena of the disorder, and expresses a belief, with which we heartily agree, that the truth resides between the two extreme opinions — the one which vaunts such agents

as panaceas against all manifestations of the disease, and the other, which considers any or all of these remedies — phenacetin for instance — as absurd and irrational in all cases.

In conclusion Dr. Mills says: The epidemic influenza has impaired the *morale* of the community. Lack of spirit in work, and an apprehensiveness with reference to health, business, and all matters of personal interest are abnormally prevalent. The hysterical have become more hysterical; the neurosthenic more neurosthenic. Hypochondria has displaced hopefulness in individuals commonly possessed of courage and fortitude. In brief, certain neuropathic and psychopathic features have been impressed upon the community. We cannot afford even to dismiss entirely from consideration the bearings of the epidemic upon the increase not only of suicides, but of other grave crimes.

RESTRICTING THE DISTRIBUTION OF SCARLET FEVER.

EARLIER in the winter the town of Brookline suffered from an epidemic of scarlet fever, which was especially active among the school children. The Board of Health, in consultation with some of the prominent practitioners of the town, took the matter in hand, and, exercising the authority delegated to it by the Public Statutes of the State as interpreted by the State Board of Health, issued a circular of advice, with some orders appended which, in connection with the usual tendency of an epidemic to eventually wear itself out by exhausting the fresh supply of susceptible material, has been followed by good results.

The period of incubation is accepted by the circular as varying from several hours to three, or possibly four, weeks. The time at which children, from a house where there has been a case of this disease, may attend school or mingle with other children, is fixed by this Board of Health, in common with others in this State, at six weeks from the commencement of the last case in the house; and no child that has visited a house in which there was at the time a case of scarlet fever, shall attend school until the expiration of two weeks following exposure. Every house infected with scarlet fever shall be placarded by a card furnished by the Board. Infected rooms and articles shall be disinfected by the Board, or by the family to the satisfaction of the Board. Another order provides against public funerals.

The circular is a good one, both in its suggestions and in its orders, but it also illustrates the difficulty of dealing with the subject satisfactorily. The *summum bonum* cannot be enforced, and an approximation to the next best thing must be aimed at. In the matter of disinfection it is recommended that sulphur be used, but its application is to be preceded by scrubbing with a disinfectant and followed by the admission of fresh air and sunshine, measures which probably insure the efficiency of the sulphur fumes.

The period of six weeks from the commencement

of the attack is probably as good an arbitrary period as any, if one must be fixed, for raising the quarantine of the individual. But the decision as to the moment when desquamation has ceased to be a source of danger, can really only be made with accuracy in each case separately, and even then it is sometimes sufficiently perplexing, as those having hospital experience with the disease well know. The difficulties of enforcing everything, are no excuse, however, for not undertaking to do something, and the local Boards of Health deserve the cordial support of their communities in these efforts.

THE BACILLUS OF INFLUENZA.

It was announced on January 7th at Koch's Institute for Infectious Diseases at Berlin, that the micro-organism of influenza had been successfully proved and cultivated. Dr. Richard Pfeiffer, chief of the scientific section, had succeeded in demonstrating a bacillus which is found only in cases of influenza, and in making a pure culture from which the disease can be induced in apes and rabbits. The same bacillus had been seen and photographed by him two years ago, but its significance could not then be proved. The reasons that this micro-organism has so long escaped detection are its small size and the difficulty in staining and in making a pure culture of it. In the cases of influenza under observation this tiny bacillus was found in immense quantities in the bronchial secretion, in uncomplicated cases in pure culture; their number keeping equal pace with the course of the disease. The bacilli appear as small rods, about half the length of the bacillus of mouse septicæmia.

Dr. Pfeiffer had only succeeded in cultivating the germ to the second generation, but Kitasato has been able to reach the fifth generation on glycerine agar. The colonies are so small that they may easily be overlooked, and possess the peculiarity of remaining separate from each other, instead of running together as is the case with the colonies of other bacteria. The bacilli themselves are immovable.

The same bacillus was discovered independently by Dr. Canon at the Moabit Hospital, and reported at the same time. Instead of searching the bronchial secretion, the blood of patients with influenza was examined. He feels justified in asserting that the micro-organism is always found in the blood of patients with influenza, at least during the stage of fever, and that it is not found in the blood of other persons.

The only suggestion for prevention or treatment of the disease based upon the discovery of this bacillus is that the sputum of patients should be carefully disinfected.

MEDICAL NOTES.

THE MEDICAL FORTNIGHTLY is the title of a new bi-monthly magazine which appeared for the first time on January 1st. It is edited by Dr. Bransford Lewis and is published in St. Louis.

NEW ENGLAND.

BOSTON LYING-IN HOSPITAL. — During the past year 527 patients were cared for in the hospital. In the out-patient department, the number of patients was 735.

DEATH-RATE IN BOSTON. — During the past week twenty-five deaths were reported as due to influenza, but all except three were complicated with some other disease. The death-rate appears to be steadily diminishing. The total number of deaths was 258, a death-rate of 29.2. The deaths from consumption were 34, pneumonia, 55, bronchitis, 24. The number of persons over sixty years of age was 48.

BEQUESTS TO PUBLIC INSTITUTIONS. — By the will of Anne W. Davis the sum of \$15,000 is given in trust, after the expiration of a life interest, two thirds of the income to be paid to the Massachusetts General Hospital and one-third to the New England Hospital for Women and Children. The will of Mrs. Elizabeth B. Bowditch contains the following bequests: The Massachusetts General Hospital, \$5,000; to establish or support a home for convalescents, \$5,000; House of the Good Samaritan, \$5,000; Children's Hospital, \$3,000; Old Ladies' Home, \$3,000.

NEW YORK.

MORTALITY FOR THE WEEK. — During the week ending January 16th, the number of deaths reported in the city was 907, which is 25 less than the preceding week, and represents an annual death-rate of 27.70 per thousand of the estimated population. The deaths from influenza and complications were 20 less than in the week preceding, being 69 in number.

SMALL-POX. — Some eight or ten cases of small-pox have recently been discovered among the Italian residents of the city, and the disease appears to have been brought from Newark, N. J., where it is said to have gained considerable headway. All the patients found were transferred to the hospital for contagious diseases on North Brothers Island, but three cases are known to have been secreted by their friends, and on the night of January 22d, a party of sanitary inspectors and policemen, headed by Dr. Cyrus Edson, Chief of the Bureau of Contagious Diseases, made an unsuccessful hunt for them among the slums.

Miscellany.

BERI-BERI.

On account of occasional report of cases of beri-beri among the fisherman on the banks off the coast of Newfoundland, the following description of the disease, as observed by Mr. A. W. Sinclair, a residency surgeon on the Malay Peninsula may prove interesting. He believes that the term beri-beri was derived from the Sanscrit "bhara," a weight, the repetition being used simply to intensify the meaning of the word. Every patient affected with the disease describes the principal symptom as a weight in his chest, legs, or

¹ Lancet, December 26th.

arms, as the case may be. Beri-beri appears in the Malay Peninsula both in the endemic and epidemic form. It principally attacks the Chinese coolies working in the tin mines, but it affects other nationalities also, and men, women and children.

In considering the etiology of the disease, the author advertises to poor living, bad clothing, poor accommodation, and exposure as among the principal causes of the disease. It seems that, in many cases at any rate, beri-beri is preceded by repeated attacks of fever, ending in swelling of the abdomen and legs. The disease commences with a feeling of malaise, followed by weakness and rheumatic pains in the joints, and a dull continuous pain in the stomach and in the knees, passing down into the feet, attended by a feeling of numbness and swelling of the parts, with oedema. Occasionally there is atrophy of the muscles of the legs, with loss of power, without any swelling, and in those cases the arms are often similarly affected. The pulse is generally soft and compressible. There is a thrill over the region of the heart, and hemic murmurs and strong pulsations in the sternal notch are present. Knee and elbow jerks are usually absent. The peculiar gait is well marked, the foot being thrown forward with a jerk and raised considerably, the toes coming to the ground first. There is generally an inclination to fall on closing the eyes and bringing the feet together. As a rule, there is no loss of sensation; sometimes there may be aphasia. There is a feeling of suffocation on laying down. The patient may die soon after the attack, or linger on for five or six months — rarely longer; he commonly dies suddenly and in much pain, described as of a burning character, in the chest and abdomen.

The post-mortem appearances are mainly indicative of congestion and enlargement of the internal organs, with dropical effusions, especially in the pericardium and oedema of the lungs. In the post-mortem examination of 100 Chinese dying of the disease the anchylostoma duodenale was discovered in the intestines in eighty instances, and distoma crassum in one. The blood of 100 typical cases of beri-beri was examined without the discovery of any micro-organism. The blood discs were found to be pale and few in number. Mr. Sinclair mentions that he inadvertently inoculated himself on one occasion, with the result that some symptoms resembling those of an early stage of beri-beri followed, but they passed away in about a week. He considers beri-beri a contagious disease induced by some micro-organism. Albumen was not present in the urine, which was in a number of cases strongly acid. Malarial cachexia was evident in all the cases. Anthelmintics were useful where internal parasites were suspected, and tonics of iron and strychnia were beneficially employed.

THERAPEUTIC NOTES.

TREATMENT OF GOITRE BY PARENCHYMATOUS INJECTIONS OF IODOFORM. — Moesig Von Moorhof treats goitre by hypodermic injections of one syringe-full of the following solution:

R. Iodoform	1 part.
Ether	as 7 parts.
Olive oil }	M.

The trocar of the syringe previously disinfected is plunged to a depth of two to three centimetres and

the injection is thrown into the parenchyma of the thyroid body. The injections are repeated at intervals of from four to six days. When the gland is very large, two or three syringefuls of the medicinal solution are injected at different parts of the tumor, the venous trunks being avoided. The local reaction is very feeble. Kapper¹ has treated fourteen patients by these injections, with marked diminution, in every instance of the volume of the thyroid after from two to four months of treatment.

ZINC GLUE FOR STIFF SURGICAL DRESSINGS.² — Treutler recommends a preparation, first suggested by Unna, for obtaining stiff surgical dressings, such as are applied to fractured or dislocated limbs. It is as follows:

R. Oxide of zinc	10 parts
Gelatin	20 "
Glycerin	30 "
Water	30 " M.

This is thickly applied and rubbed into the muslin or gauze forming the bandage. A thinner preparation contains twenty parts of gelatin and forty parts of water, the other ingredients remaining the same.

Correspondence.

THE TREATMENT OF CHRONIC SPRAINS OF THE FINGER-JOINTS.

BOSTON, January 22, 1892.

MR EDITOR: — By the JOURNAL of the 21st instant I am pleased to learn that Dr. Lovett has met with considerable success in the treatment of chronic sprains of the finger-joints. Many such cases have been sent to me for massage by physicians; and I am sorry to say that I have had but little success; indeed, I fear that I have even made some of them worse by over-zealous attempts at passive motion. It is rather puzzling why chronic sprains of the finger-joints should prove more intractable to treatment than chronic sprains of some other joints. They have no weight to carry, as do the joints of the lower extremities, chronic as well as acute sprains of which generally do well under treatment by massage. The less the objective symptoms about a joint the harder it is to relieve pain, which in some cases is probably due to neuritis.

The subject of Dr. Lovett's paper is not one of recent acute sprains, still it may be allowable to speak of them here. Even severe cases of this class do remarkably well under immobilization and massage from the very first, once or twice daily, removing the fixed dressing for this purpose. Under this combined method of treatment there is generally free use of the joint in seven or eight days. The orthodox treatment of absolute immobility alone in these cases has little else to support it than the dogmatism of centuries, from which it is almost impossible for a surgeon to free himself unless he has been the unfortunate victim of a sprain and had it treated with massage, and immobilization if necessary. Supposing that any one wanted to make a well joint stiff, to what more effectual means could he resort than first to give it a wrench or sprain, then do it up in a fixed dressing, so that the resulting inflammation would have an opportunity to produce adhesion of the tissues? The same plan of treatment is employed for the purpose of closing up a hole, namely, that of exciting adhesive inflammation, and unfortunately it sometimes closes the cavity of a joint also. Massage in recent sprains speedily removes the heat, the pain, the swelling, and prevents the formation of adhesions. The mode of applying it I have frequently described.

Very truly yours,

DOUGLAS GRAHAM, M.D.

* O, cloudy; C, clear; F, fair; G, fog; H, hazy; S, smoky; R, rain; T, threat; ening; N, snow. + Indicates trace of rainfall. — Mean for week.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 15, 1892, TO JANUARY 22, 1892.

Leave of absence for twenty-one days is granted MAJOR ROBERT M. O'REILLY, surgeon, U. S. A., Fort Logan, Col.

CAPTAIN LOUIS BRECHMEN, assistant surgeon, U. S. A., will proceed, without delay, from the Presidio of San Francisco, Cal., to Vancouver Barracks, Wash., and report in person to the commanding officer of that post for temporary duty.

CAPTAIN AARON H. APPEL, assistant surgeon, U. S. A., is relieved from duty at Fort D. A. Russell, Wyo., and will report to the commanding officer, Fort Buford, N. D., relieving FIRST LIEUTENANT JULIAN M. CABELL, assistant surgeon, who will then report in person for duty at Fort D. A. Russell, Wyo.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 23, 1892.

W. G. FARWELL, surgeon, detached from Naval Hospital, Norfolk, and wait orders.

DRAKE, passed assistant surgeon, ordered to the Naval Hospital, Chelsea, Mass.

GEORGE McC. PICKRELL, passed assistant surgeon, detached from Naval Hospital, Chelsea, and to Naval Hospital, Norfolk.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE FOUR WEEKS ENDING JANUARY 16, 1892.

IRWIN, FAIRFAX, surgeon. Granted leave of absence for seven days. January 13, 1892.

CARTER, H. R., passed assistant surgeon. To proceed to Cincinnati, O., and assume command of the service. January 8, 1892.

BROOKS, S. D., passed assistant surgeon. To inspect unserviceable property at Marine Hospital, Detroit, Mich. December 23, 1891.

WILLIAMS, L. L., passed assistant surgeon. Granted leave of absence for twenty days. January 12 and 13, 1892.

PETTUS, W. J., passed assistant surgeon. To proceed to

Buffalo, N. Y., and assume command of the service. December 21, 1891.

MAGRUDER, G. M., passed assistant surgeon. Relieved from duty at Washington, D. C.; ordered to Marine Hospital, New Orleans, La. January 8, 1892.

PERRY, T. B., passed assistant surgeon. To proceed to Cape Charles Quarantine for temporary duty. January 13, 1892.

DEATH.

LONG, W. H., surgeon. Died at Cincinnati, O., January 5, 1892.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.—A regular meeting will be held at 19 Boylston Place, on Monday, February 1, 1892, at 8 o'clock.

Read: Dr. E. S. Wood, "Renal Albuminuria not Due to Organic Disease of the Kidneys"; Dr. C. P. Worcester, "The Relative Values of Certain Meat Extracts."

JOHN C. MUNRO, M.D., Secretary.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.—This Section will hold its regular monthly meeting Wednesday evening, February 3, 1892, at 19 Boylston Place.

Papers: Dr. E. H. Bradford, "Operations on the Tarsus for Club-Foot"; Dr. A. M. Phelps, of New York City, will describe his "Method of Open Incision for Club-Foot"; Dr. Augustus Thorndike, "The Case of Club-Foot in the Adult"; Dr. John H. Hudspeth, "Pott's Paralysis"; Dr. Wm. N. Bullard and Dr. C. L. Scudder, "Spastic Paralysis"; Dr. E. G. Brackett, "Torticollis Due to Hemiatrophy of the Sterno-Cleido-Mastoid Muscle."

CHARLES L. SCUDDER, M.D., Secretary.

NORFOLK DISTRICT MEDICAL SOCIETY.—The fellows of the Norfolk District Medical Society resident in Jamaica Plain will entertain the Society at the Club House of the Jamaica Club, on Saturday, January 29th, at 7.45 p. m. [Please note change of date.]

Dr. E. W. Hill, "Some Cases of Malarial Epilepsy. Advantages of Sulphonate Treatment of Epileptics." To be followed by general discussion upon Epilepsy by Drs. W. Channing, J. H. McCollum, S. J. Mixter, H. R. Stedman and others.

Collation at 9.30.

The Club House is located on Green St., corner of Rockview Street, Jamaica Plain, three minutes walk from Rockview Railroad Station. Train from Boston at 7.35 p. m., return at 9.27, 10.40, 10.50. The electric cars of the Jamaica Plain and the Egleston Square lines stop at Green Street, at short intervals.

JAMES C. D. PIGEON, M.D., Secretary.

RECENT DEATHS.

CLAUDIUS MARCELLUS JONES, M.D., M.M.S.S., died at the Massachusetts General Hospital, January 24th, aged forty-six. Dr. Jones was born in Worcester in 1845, and graduated from Harvard College in 1866. He spent some years in teaching before entering the Harvard Medical School, from which he graduated in 1875. He served for a year as house-officer at the Massachusetts General Hospital. He was, at the time of his death, physician to the Boston Dispensary, the House of the Good Samaritan and St. Monica's Home.

DANIEL AYRES, M.D., died in Brooklyn, N. Y., January 18th, aged seventeen. He graduated from the University of New York in 1844, and received the honorary degree of LL.D. from Wesleyan in 1856. He was Surgeon and Professor of Clinical Surgery in the Long Island College Hospital until 1874, when he was made Professor Emeritus.

JOHN WITT RANDALL, M.D., died in Boston, January 29th, aged seventy-eight. He graduated from Harvard College in 1834, and from the Medical School in 1839. He devoted most of his life to the study of natural history, especially entomology.

EUGENE MONTARD-MARTIN, M.D., Physician to the Hôtel Dieu, Paris, President of the Académie de Médecine in 1890, died recently in Paris, aged seventy.

BOOKS AND PAMPHLETS RECEIVED.

Diseases of the Bladder and Prostate. By Hall C. Wyman, M.Sc., M.D. Detroit; George S. Davis. 1891.

Atlas of Clinical Medicine. By Bryton Bramwell, M.D., F.R.C.P., F.R.S., Assistant Physician to the Edinburgh Royal Infirmary. Volume I, Part III. Edinburgh: T. and A. Constable. 1891.

The Prescriber's Pharmacopœia, a Synopsis of the More Recent Remedies with a Therapeutic Index. By a member of the Pharmaceutical Society of Great Britain. Second edition. Bombay: Kemp & Co. Limited. 1891.

Original Articles.**SOME DANGERS OF INFECTION INCIDENTAL TO PROFESSIONAL LIFE.¹**

BY JAMES C. WHITE, M.D.,
Professor of Dermatology in Harvard University.

I HAVE been consulted within the last ten years by so many physicians on account of diseases they have acquired by contact with patients, that I have thought that it might not be without interest, and perhaps profit to members of the Society, if I were to present to them in a brief form some of the dangers to which they are thus especially exposed. It is not my intention in this communication to consider what possible relation every disease regarded as contagious or infectious may bear to our subject, but I shall confine my remarks to those affections which are largely, if not wholly, acquired by contact alone. I shall exclude, therefore, all mention of the so-called acute contagious or infectious fevers, the liability and consequences of acquiring which are well understood. It may be well also to state in the beginning that I shall use the terms infection and contagion indifferently throughout this paper. I shall make no attempt to present my subject in any systematic order.

ANIMAL PARASITES.

But little need be said with regard to the danger of acquiring any of the affections of this group. Of the three forms of pediculosis it is the variety *capillitii* only which the physician is liable to. It is by no means an uncommon occurrence for him to "get lice," as the expression is, in the performance of auscultation, chiefly among the poorer classes in cities, with whom it is extremely prevalent, and to carry it home to his family. It is the wife, however, generally who is the chief sufferer in such cases, for it is in her longer hair that the parasite finds the more favorable conditions for breeding, whilst in the very short hair of the doctor, as now worn, it rarely establishes a permanent seat. I have known not a few such instances in the households of members of this Society.

Scabies is the only other form of animal parasitic disease which the physician is liable to acquire by contact with patients, for although he may often be annoyed by the bites of bugs and fleas, so frequently found in the homes and upon the persons of the poor and dirty, their brief action upon his skin is but a trifling matter. The itch, however, is a much more serious affair, and as it has become a very common affection amongst us in the last few years (sixty-one cases seen at my clinic since October 1st), and as physicians often fail to recognize it, even in the most exaggerated cases when consulted, opportunities for its acquisition by themselves cannot be infrequent. Their exemption under these circumstances (for in my experience such cases of transference are not common, I can recall but one or two) is due, no doubt, to the fact that patients with scabies are handled at the dispensary or consult-on-room when their hands and general surfaces are by exposure at a lower temperature than is conducive to the activity of the parasite, and because contact with the affected parts during a professional examination is necessarily very brief. Transference

of the animal from one person to another is most generally effected, no doubt, by holding the hand for some time, or by longer surface contact with other affected parts of the body in bed, or during impure sexual intercourse. All possibility of such infection can be positively removed by adopting the custom of washing the hands immediately after handling any suspected patient.

VEGETABLE PARASITES.

When I was a young physician I wrote a Boylston essay upon human parasites, and this portion of my subject then comprised only three surface forms of fungus disease. Now we know that the class of vegetable parasites has been greatly enlarged, and includes some of the most important and fatal affections. Those forms were the easily recognized *tinea favosa*, *tinea trichophytina* and *tinea versicolor*. I have known but a single instance of the probable communication of any of these mycoses to the physician by ordinary contact with patients. This was a long continued *tinea trichophytina* of the finger-nails. The other two forms are transferred from person to person with the greatest difficulty, even when inoculation is intentionally practised. All the forms may, I believe, be freely handled and examined with impunity, provided the hands and instruments be immediately and thoroughly washed after contact.

There are two affections as to the contagious character of which there can be no doubt, and which are frequently transferred from animals to man. These are anthrax and equinia.

Anthrax.—The former, or splenic fever of horned cattle, sheep, horses and rabbits, is capable of causing internal general anthrax in man by inhalation of the infectious material, the *bacillus anthracis*, an wool-sorster's disease, without any accompanying cutaneous manifestations, as well as the so-called malignant pustule, by direct inoculation, as seen in butchers, grooms, tanners, skin-dressers, and the like. It is apparent that the veterinary surgeon is also liable to acquire the disease by the care of affected animals, or by post-mortem examinations of the same. It is also evident that the physician may become inoculated by the dissection of patients who have died of the disease, but a question of more general interest is whether he may become infected by contact with its external forms upon man. I find no record of such transferrence from patient to physician, but I see no improbability in its occurrence.

Equinia.—In glanders also we have a bacillus disease which is readily transferred from horses and asses to man, and from the latter to animals again by inoculation. As it not infrequently affects grooms, so, too, the veterinary surgeon is especially in danger of acquiring it. The virus may also be received by driving behind an affected horse, through contact of the spray from the beast's nostrils with the mouth or eye. In the acute form of farcy in man only about one-third of the cases recover. A few instances are on record where it has been transferred from man to man. It is possible, therefore, that the physician may be inoculated during attendance upon a patient.

Diphtheria is another bacillus disease which has been often transferred with fatal results from patient to physician, generally accomplished by sucking out bits of membrane after tracheotomy. Two members of this Society have become infected during attendance

¹ Read before the Boston Society for Medical Improvement, December 14, 1891.

upon patients, one fatally, by such direct inoculation. It should not be forgotten that the Klebs-Löffler bacillus may persist in the mouth for ten or more days after the disappearance of the membrane in the throat, and that the vitality of these germs may remain active for months after their removal from an animal basis.

Gonorrhœa. — The dangerous consequences to the eye of the surgeon of contact with the specific discharge in gonorrhœa must not be omitted from this list of infective accidents.

Erysipelas. — With regard to the contagious character of erysipelas diverse opinions prevail, although there is no longer a question as to its parasitic nature. The micrococcus is found in the lymphatic vessels and spaces in all cases, and has repeatedly reproduced the disease after cultivation when inoculated into the healthy skin of man. One understands, therefore, how the affection might be transferred from person to person, from patient to physician. Common belief has it that there is great danger of such communication, an opinion largely held apparently by our profession as well. I do not doubt the possibility of such transference, but I believe that it rarely occurs; I refer to the ordinary superficial forms of the affection. In the great number of cases that I have treated I have not known a single instance in which a second member of the family, a nurse, or medical attendant has become affected. At a meeting of the American Dermatological Association, held a few years ago, during a discussion upon the disease I asked if any of the twenty dermatologists present had personal knowledge of such an occurrence, and but one member could reply that he had observed a case in which such communication seemed to have taken place. Considering the frequency of the disease, we may conclude that erysipelas is contagious in a very feeble degree only. Considering its frequency, we must also conclude that the germs are often at hand to gain entrance through some unprotected point, as the chronic picked or sore nose, sore eyelid, or other abraded and exposed surface. This almost necessary connection with traumatism must largely account for its prevalence in the surgical wards of hospitals. Practically, the physician with a sound epidermis is sufficiently protected against the contagion of erysipelas.

Actinomycosis. — Now that we know that the ray fungus, a streptothrix, — which produces in domestic cattle "wen," "osteo-sarcoma," "bony sarcoma," and "wooden tongue," in the horse "scirrous cord," in the pig abscesses in the milk glands and about the pharynx, — is also capable of producing disease in the tissues of man, the alveoli, the tonsils, the glands, lungs, and bones, and that it may be cultivated and thereafter successfully inoculated into rabbits and other animals, we have one more possible source of infection to avoid in the manipulation of disease. Our knowledge of the existence of actinomycosis in man is of too brief duration to furnish the clinical data, by which the reality of such danger may be estimated.

Rhino-scleroma must not be omitted from our list of bacillus and possibly infectious diseases, but it is extremely rare, and, so far as I am cognizant, we have no evidence of its transference from one person to another.

Leprosy, Tuberculosis, Syphilis. — There remain to be considered in their positive relations to our subject three of the most important diseases which affect man, and which are the chief destroyers of the human race. These are leprosy, tuberculosis, and syphilis. The first

two are known to be bacillus affections. The latter has not yet been demonstrated to be such, as the first had not been in 1879, and the second in 1881. Still, the bacillus was present in them all the while previous to these dates, just as I doubt not one has always been, and is in the tissues of every case of syphilis. We shall yet find the proper reagent for its recognition. All three of them are contagious in the sense of being communicable from one person to another under favorable conditions, by contact or inoculation. The question which immediately concerns us is, how far does ordinary professional intercourse between the physician and the patient make such transference possible?

Lepra. — In a communication made to this Society a year ago, I presented the evidence upon which modern belief in the contagiousness of leprosy is founded. These data, very briefly restated, were: a study of the history of the introduction of the disease into Europe in the twelfth and thirteenth centuries, and its disappearance under stringent laws of segregation; its lingering in force in certain civilized countries under the protective patronage of the doctrine of heredity, and its rapid shrinking from 3,000 to 800 cases in the same regions under a revival of the practice of isolation in the present generation; the enormous spread in our day of the disease on fresh introduction among virgin nations, whose customs and morals especially favor its transference by personal contact; the opportunities afforded of studying its restricted spread along family lines on its recent appearance in certain limited foci in the United States and adjoining British Provinces; and lastly, numerous well authenticated instances of servants, ward-tenders, nurses and priests becoming affected by the disease after prolonged attendance upon hospital lepers. In fact, I do not hesitate to state that we are acquainted with many more cases of leprosy acquired by hospital attendants than with instances of syphilis similarly communicated to nurses and ward-tenders in syphilitic wards. Nor should the successful results of the inoculation of the condemned murderer, by Dr. Arning, in the Hawaiian Islands, although not an absolute demonstration, be forgotten.

The presence of bacilli in all affected tissues, in the secretions and discharges, and the open condition of the numerous cutaneous lesions in leprosy, offer the most favorable conditions for inoculation on the part of the patient throughout the prolonged course of the disease. On the other hand, the protracted period of incubation after inoculation, from one to five years probably, makes the recognition of such instances of direct communication vastly more difficult than in syphilis. If these nurses and ward-tenders and priests may and do become lepers, in consequence of their attendance upon lepers, it is evident that physicians may also acquire the disease by personal contact with patients. Two Hawaiian physicians, not natives, are known to have become affected by it.

But, it may be said, this is a very remote danger to ourselves as practitioners, for leprosy is not a disease of our part of the world. It is true that there are not 250,000 lepers in the United States, as there are in India, and that they do not form considerate percentage of our population, 1:15, as in the Sandwich Islands, yet the disease has established a foothold in many of our States — in South Carolina, Florida, Louisiana, Texas, California, Oregon, Wisconsin, Minnesota, Dakota, and Utah. Last year there

were certainly six cases in New York City, four in Philadelphia, and two in Boston. These are the cases that have been recognized; they are but a part only, no doubt, of the number that really exist amongst us. Fifteen years ago it was scarcely known that outside of our Scandinavian States there was a leper in the country; now there are one hundred in one town in Florida alone. The disease is bound to increase with all these foci in our midst, if the national government do not take immediate steps for its exclusion by proper immigration laws, and for its segregation within our boundaries, while it yet remains in manageable numbers. Practically, there need be no dread on the part of the physician to handle any case of leprosy in the freest way under a few simple precautions: that the epidermal covering of his hands is intact, that he never allows himself to touch an excoriated lesion or the various discharges of the patient, and that he invariably washes his hands in the most thorough manner after his examination of every case.

Tuberculosis. — I have so lately expressed my views² concerning the unity and contagiousness of the several phases of this disease of many shapes, that I hardly need say more with regard to their recognition and interchangeable nature. In lupus, verruca necrogenica, tuberculosis cutis, and scrofuloderma, as in other forms less commonly well known, we find the same bacillus, the same as in tuberculous disease of other organs, capable of cultivation and of producing one and the same disease in animals on inoculation, from whichever of these clinical forms it is taken. Conclusive evidence has been collected moreover that one form may produce the same or another when inoculated or transferred from one tissue to another tissue of the same person, or to the tissues of a second person. The common nature and the common danger of all forms of tuberculosis having been established, the question which especially concerns us now is in what way and in what form is the disease most likely to be communicated to the physician or surgeon. We know the possible dangers incident to the inhalation of the air of wards for consumptives up to the recent date of our knowledge concerning the nature of sputa at that disease, and those connected with auscultation and other forms of close contact with contaminated garments and the patient's exhalations. There are other channels of infection not so generally appreciated.

The verruca necrogenica, or anatomical tubercle, has long been known as affecting the fingers of dissectors and autopsy-makers, but it is only within a few years that its tuberculous nature has been known. Lately a much more extensive verrucose affection of the integument has become recognized also as a true cutaneous tuberculosis, and entitled tuberculosis verrucosa. Both forms contain the tubercle bacillus, and are in fact anatomically identical in all respects. The first named clinical form is undoubtedly acquired in the dissecting and necropsy rooms by contact with tuberculous tissues of the cadaver. The latter, much more extensive and sometimes multiple, is often acquired, I believe, by contact with phthisical sputa and open scrofulous glands. I have seen it repeatedly upon the hands of consumptives, and those in attendance upon them and patients with scrofulous ulcers. One may therefore acquire cutaneous forms of tuberculosis by making dissections and autopsies, by examinations of all external forms of the disease, by surgical opera-

tions upon "scrofulous" gland, bone and joint disease, and by contact with phthisical sputa. That cases of inoculation among physicians, considering the great prevalence of these many forms of the disease, are not more common, may be attributed to the protective nature of a sound epidermis. That none of us may surely escape such danger will be apparent to you, when I state that two members of this body have thus acquired tuberculosis verrucosa, and I have treated several students with verruca necrogenica. It is indeed fortunate that such forms of the disease tend to remain strictly localized cutaneous processes for indefinite periods, and not to become foci for dissemination of the bacillus to internal vital organs, as do the softening varieties, lupus and scrofuloderma, in so large a percentage of cases.

Syphilis. — This is an affection, with the appearances of which the practitioner is presumed to be familiar, and with the dangerously infective properties of which he is fully acquainted. It might be supposed, therefore, that, being constantly upon his guard, it would be a rare occurrence that he should become infected through patients. Unfortunately the reverse is the case. This may be due to lack of proper knowledge of all the manifestations of this protean disease, to inattention to the necessary precautions in handling cases, or to the masked or concealed lesions with which he may come in contact during surgical or obstetrical manipulations. Certain it is that for one or all of these reasons physicians often become inoculated with syphilitic virus through their own hands. Another unfortunate feature in the history of these cases is that they rarely recognize the real character of the early lesion upon themselves, accepting every possible and often impossible diagnosis as to its nature, before the correct one is forced upon them. They, too, are apparently blinded by the commonly received opinion that syphilis is necessarily a venereal disease, and therefore disregard the liability of contracting it through extra-venereal channels, and the dangers of contact with other than genital lesions. Accordingly the digital primary lesion is generally regarded as a felon, a septic sore, a local tuberculosis, or even a malignant process at first, or until a perfectly defined syphilitoderm, or other signs of general infection, make clear the nature of the former. I have seen all these mistakes made, and, when the later constitutional symptoms were slight or fugitive in character, have seen the erroneous diagnosis persisted in for months, in one instance until amputation was seriously considered by patient and surgeon as the only possible means of relief. It is astonishing how wide and deep may be the tissue changes in the integument, which in time develop around the primary inoculation in some such cases. In the beginning, however, the earliest manifestations may be of the most insignificant and apparently trivial character. The primary lesion of syphilis is by no means necessarily the expected standard chancre, it may be a small papule, an excoration, or an ulcer of very misleading appearance. It is not, however, my intention even to touch upon the diagnostic features of any of the affections we are considering. I have notes of fifteen cases of syphilis in physicians, and I have seen and known of others, who were inoculated upon the hands during the discharge of their professional duties. The seat of the primary lesion was determined in the majority of them by inspection, in the remainder by data obtained from the

victims. They were mostly severe cases, perhaps because, for reasons above given, the diagnosis was made late and, therefore, treatment was begun late, perhaps because there is truth in the common saying that physicians make bad patients, and treatment under the divided responsibility of the consultant and sufferer was negligently conducted. I know no disease which demands so absolute and constant a surrender of the patient's will to the control of the physician as syphilis. Three of these unfortunates, possibly more, died of the disease. All of them suffered greatly in mind, and were more or less physically disabled or disfigured for a time. Some of them might readily have communicated the disease to their own households or to patients, before the nature of the digital affection was recognized. I once treated a midwife with an open primary lesion upon her finger. I found that she had delivered thirty-two women whilst the sore was in this condition. How many of these lying-in women, or of the infants handled by her may she not have infected? Yet I believe that every case of syphilis may be handled as thoroughly as the needs of diagnosis demand. The sound epidermis is a safe shield against the reception of the virus as a rule, no doubt, but the hang-nail, or the slight fissure, or excoriation forms the fatal point of entrance.

Two practical lessons have enforced themselves upon me from my experience in this relation: First, always to wash one's hands immediately after an interview with a patient who has, or is suspected to have syphilis, without regard to the condition of the parts handled, or even if not touched at all. This should be made an invariable custom. Second, that the physician should regard every persistent sore upon himself of whatever seat and however innocent apparently, as a possible lesion of tuberculosis or syphilis, and seek competent advice without delay. Such advice is never found at home.

I have thus briefly, and very inadequately, I am aware, called your attention to some of the dangers to which the physician is liable in his daily work. The agents of all the evils we have been considering are among the most minute and lowest forms of organized life. In spite of recent disappointments in the resources of pure science applied to this end by the most eminent masters, let us not forget that one most destructive pest was long ago robbed of power over mankind by the keen observation alone of a plain country physician, and trust that, in the one way or the other, some day these afflictions, we have been considering, may likewise be rendered innocuous to us and all men by the protective action of some beneficent influence.

WHAT IS A "FELON"?¹

BY HERBERT L. BURRILL, M.D.,

Assistant Visiting Surgeon, Boston City Hospital; Instructor in Clinical Surgery, Harvard University.

As a member of the Suffolk Board of Censors I have asked the above question of many applicants for admission to the Massachusetts Medical Society, and have received answers which have convinced me that the term "felon" is loosely applied. A search in the common text-books on surgery shows, as a rule, the neglect to clinically differentiate the inflammatory diseases of the finger.

¹ Read before the Boston Society for Medical Improvement, December 14, 1891.

There can be no question of the difference between a simple "run-round," which, although troublesome, is rarely dangerous, and that serious, destructive suppuration which destroys not alone the usefulness of the finger and hand, but occasionally ends fatally. Yet the distinction in name, at least, is frequently not made. I feel sure that most practitioners distinguish various affections of the fingers; and in this paper I shall place before you a classification that I have used in my work, which has enabled me to meet these cases with a greater sense of accuracy. It is an anatomical classification, and is as follows:

- (1) Dermatitis.
- (2) Paronychia.
- (3) Cellulitis of the finger.
- (4) Suppurative theritis.
- (5) Periosteitis, or osteitis of the phalanges.

I believe that it will be granted by all that it will be of value to differentiate these several affections, and, as a matter of fact, I have found it possible to do so in my clinical work. Whether I shall succeed in placing their clinical histories before you will be a matter of which you alone can judge.

I. DERMATITIS.

In a dermatitis we have a clinical history somewhat as follows: Usually the starting-point is some slight abrasion of the cuticle covering the end of the finger, and from this point there starts a reddened area with slight elevation of the skin, with a stinging, smarting pain, which is not intense enough to prevent sleep. The finger when held dependent is more painful than when supported. This red, slightly elevated area involves both the epidermis and the derma. Vesicles form from point to point, these become pustules, and the dermal inflammation which extends is temporarily checked at the different flexures of the fingers until it involves the whole finger, and occasionally spreads on to the palm or dorsum of the hand. Copper workers, zinc workers and paper-box workmen are particularly apt to have this trouble. It is purely a local affection, and is self-limited when the cause is removed. Its treatment may be carried out by the application of any one of the astringent lotions like liq. plumb., subacet., or, what is preferable, a 1-20000 solution of corrosive sublimate. This, in the course of forty-eight to sixty hours, will check the dermal inflammation, as a rule, and then exfoliation of the skin of the finger will occur.

II. PARONYCHIA.

This is a form of inflammation which occurs in the structures lying at the root of a nail, and it may appear when any crack has occurred in the skin overlying the luna of the nail. Usually a smarting, stinging, or throbbing pain exists for a few hours, definitely localized in a tender, reddened area at the point of infection; for I believe that usually this is the result of inoculation. (House-surgeons used to be particularly liable to this affection, but of late years have had less trouble). At the end of one or two days there is usually a small area of pus, and at this time by appropriate surgical interference a great deal of trouble can be averted. If, on the other hand, this is neglected the pus is retained by the tense band of the union of the derma at this point, and passes downward to the matrix of the nail, and then begins to burrow beneath the nail. This occurs at the end of four or five days,

until finally the matrix of the nail is completely undermined, and the nail is thrown off at the end of several weeks or months. This process may stop and the pus be discharged from beneath the skin covering the luna of the nail, in which case the nail is not lost. When, however, the process passes down beneath the nail the pus continues to discharge, at times changing to a thin, straw-colored fluid, the skin at the root of the nail becomes a livid white, is sodden and saturated with purulent material, until relief is afforded by allowing a free exit for the retained fluids.

The early treatment of this affection is very simple. The part of the skin overlying the luna should be thoroughly divided, so that pus is evacuated. It may be necessary to use primary anesthesia or cocaine. Then a moist, hot, antiseptic dressing¹ should be applied and changed once in four hours, and usually at the end of twenty-four to forty-eight hours wrinkling of the skin, subsidence of redness and pain having occurred, the process is checked. After this a dry dressing, like aristol, can be used to advantage; but if there is any recurrence of active inflammation, a moist, hot, antiseptic dressing should again be used.

Not infrequently this simple treatment is futile, for as soon as the moist, hot, antiseptic dressing is resumed the soft parts at the root of the nail become actively inflamed again, and when this occurs one may abandon an antiseptic dressing, and attach the free end of a narrow strip of adhesive plaster (three-eighths to half an inch wide and four-fifths of an inch long) to the side of the finger, and wrap it around the finger in a spiral. This attachment of plaster draws away the skin from the nail, and into the sulcus nitrate of lead may be dusted. This "drys" up the discharge, and is of assistance in checking an obstinate inflammation at the root of a nail.

When the pus has passed down beneath the nail, or the end of the finger has become sodden and club-shaped from the retained purulent material, the nail should be removed, care being taken to remove the lateral expansions at the root of the nail; this allows a free exit of the pus, and the use of any antiseptic dressing will quickly put the finger on the road to recovery. Nails grow in from four to six months.

III. CELLULITIS OF THE FINGER.

In the clinical history of this affection there is usually a story of a contusion or a direct inoculation by a pin or needle, and then within twelve or twenty-four hours there begins a throbbing pain distinctly localized at one point on the palmar surface of the finger. This gradually becomes reddened, slightly dusky, and the whole finger end becomes tense from the swelling. The throbbing pain continues, but is rarely sufficient to keep the patient awake the first, or even the second night. By the third night the pain is usually so intense that the patient will have simply "cat-naps." Usually before this a poultice has been applied, and the pus has more or less localized itself at some point on the extremity of the finger.

The treatment is simple, not imperative. It requires a limited incision into the pulp of the finger; a thorough evacuation of the pus; and the application of a moist, hot, antiseptic dressing.

¹ This should consist of clean gauze or absorbent cotton wrung out in a solution of 1-2000 of corrosive sublimate; should be generous, so that by its extent and bulk it may macerate all the surrounding parts, and it should be enveloped in some form of "protective," as oil muslin, macintosh or oiled paper, that the heat and moisture may be retained.

Even if an incision is not made in the finger, after a proper amount of poulticing the pus will evacuate itself, and, although, possibly an unpleasant scar will be left on the finger no permanent impairment of the finger tip will occur; so that the prognosis of this affection is good.

IV. SUPPURATIVE THECITIS.

This affection may be due either to direct inoculation by a needle or pin; severe bruising of the soft parts overlying the tendons; or a long-continued use of the flexor tendons in a patient unaccustomed to their use; for instance, stone-masons who have been out of work for a time, and who on returning to their work have to handle rough stones which they have grown unaccustomed to, occasionally start up a serious suppurative thecitis which involves the fingers and palm of the hand.

The clinical history is as follows: A pulsating, throbbing pain referred to the whole finger is one of the first symptoms noticed. It comes often before much swelling occurs in the finger, and certainly before redness makes its appearance. This throbbing pain is severe, but for the first twenty-four hours does not keep the patient awake. With intelligent patients I have found that they could define accurately the limits of the suppurative process in the sheath of the tendon. Pressure laterally on the finger is painless, while pressure on the tendon is very painful.

The spread of the inflammation up the course of the tendon is delayed at the flexures of the fingers, and starting, for instance, in the middle finger in the second joint, it is usually forty-eight hours before the thecitis has spread to the palm of the hand. The finger is flexed on itself in order to render it less tense, and by the end of the third day the whole finger is involved in the process, and usually relief to the severe throbbing pain occurs suddenly by the bursting of the sheath of the tendon, and thus direct infection of the surrounding cellular parts occurs.

If no relief is afforded by surgical measures the whole finger is soon involved. It becomes tensely swollen; a livid red; exquisitely sensitive; the entire finger assumes the shape of a sausage; the joints are involved in the suppurative process; the sheath of the tendon becomes loaded with pus, and utter destruction of the finger is the result.

If the pus confines itself alone to the finger it will be most fortunate, but usually the inflammatory process extends upwards along the course of the tendons into the palm of the hand, beneath the annular ligament and into the forearm; until the palmar fascia is tensely distended, and the forearm and arm filled with channels of pus. When it reaches this stage often the patient succumbs to the absorption of purulent material, or at best escapes with a hand and forearm crippled by the permanent gluing down of the muscles and tendons.

The treatment of this affection differs so widely from the two preceding ones that it is on this account that I speak so strongly in reference to a division of the diseases known and classed under the head of felon. The earliest surgical interference under ether, with careful antisepsis, will save the finger and the usefulness of the hand.

Any patient who has an early clinical history of thecitis, I should advise to take ether and have a careful incision made down to the sheath of the tendon, which

if found distended can be thoroughly opened, and if necessary further openings can be made at other points in the course of the tendon and the pus allowed to escape. Then the surface should be thoroughly cleansed with an active germicide, 1-2000 corrosive sublimate, and the finger and hand immersed in a hot, moist, antiseptic dressing. Immobilization of the fingers, hand and arm are imperative; for under these circumstances the slightest motion in the flexor tendon may inoculate a fresh surface in the tendon sheath.

If, on the other hand, after making an incision down to the flexor tendon, at the end of twelve or eighteen hours we have no distension of the sheath of the tendon, useless or indiscriminate cuts, which I regret to say are not infrequently made into the palmar surface of the finger, may be avoided. I have notes of four cases where I believe a simple cellulitis of the finger was converted into a suppurative thecitis by an incision made "down to the bone." In one instance the patient's life was sacrificed; in the other the pus extended into the deeper structures of the forearm, and permanently impaired the usefulness of the arm and hand.

The treatment of these cases, when the pus has involved the palm of the hand and forearm, should be by free incisions into all the available parts. These various incisions can be enlarged by Bigelow's dilator, which is like a glove stretcher, and drainage-tubes should be placed connecting the various openings. The hand and arm should then be treated with a hot, moist, antiseptic dressing, changed frequently, or by a continuous antiseptic bath, which is a very useful measure in the severer cases. Amputation of the arm is exceptionally called for.

The prognosis of this affection, if seen early and treated promptly and surgically, is good. A certain amount of stiffness of the finger, the sheath of which has been opened, will remain for a limited period of time; but massage, and a constant use of the hand after healing, will at the end of a few months nearly restore the finger to usefulness. Where, however, the pus has extended into the palm of the hand, and especially when it has involved the wrist and the deeper structures of the forearm, a most guarded prognosis must be given, not alone as regards the use of the arm, hand and fingers, but as to life itself.

V. PERIOSTEITIS, OR OSTEITIS OF THE PHALANGES.

The clinical history of a periosteitis or osteitis of the phalanx is different from the preceding histories. As the result of some contusion, or occasionally by direct infection, we have, usually beginning in the evening, a severe pain definitely localized at some one point on the extremity of the last phalanx. This pain is so intense that sleep is out of the question. The finger may be slightly tense and perhaps glistening, but any marked degree of swelling has not occurred. The pain is so intense that the patient walks the floor, holding the hand and writhing with pain. This continues at varying intervals for from twenty-four to forty-eight and up to sixty hours, when the pain diminishes, the finger becomes more swollen and distended, and of a vivid red color. This relief to pain is due to the bursting of the periosteum, and letting out of the pus into the surrounding parts; then we have added to the osteitis or periosteitis a cellulitis of the soft parts of the finger.

When the pain has persisted longer than three or

four days, or has not been relieved by a free incision, I have inferred that there was an inflammation of the bone itself. Blisters then form on the tip of the finger, until finally pus is discharged, and the finger is converted into a rounded nub of a livid red color, and finally, at the end of from eight to twelve weeks, there is cast off the sequestrum of the necrosed bone. The mischief to the bone in these cases is done very quickly; for it is a form of jugulation of the phalanx that occurs from the pus collecting beneath the sheath of the periosteum.

After the sequestrum has been cast off, at intervals varying from four to eight months, the finger heals, leaving a misshapen extremity, a distorted, curved nail, and a permanently impaired finger-tip.

The treatment of this affection is one requiring the promptest surgical interference. In seven instances I have made a direct incision into a finger within twelve hours of the beginning of the pain, and in each instance found a small area of pus. Here, in each case, the incision was carried directly down to and through the periosteum. In two instances there was not complete relief to pain for two or three days. My belief is that in these cases the original trouble started in the osseous structure of the finger. If the incision is made early and thoroughly, we can frequently save the bone from becoming necrosed; but at the end of forty-eight hours I have found the bone irremediably damaged; and if a patient comes to me with a periosteitis or osteitis at the end of four or five days, I always warn them that the bone has been destroyed by the inflammatory process. This is an important point, for the patient often thinks that the surgical interference is the cause of the loss of the phalanx.

In those cases which come at the end of four or five days with the finger tensely swollen and filled with pus, a free incision hastens the recovery of the parts. In two instances I have removed the phalanx at this time endeavoring to save the periosteum, and in both instances have had a reproduction of a certain proportion of the phalanx.

Where a patient applies for relief at the end of several weeks, with the finger swollen, livid and distended with pus, which has opened at various places about the end of the finger, on introducing a probe one can feel the bare bone, and an operation is necessary for its removal. A certain amount of shaping can be accomplished by adjusting a finger splint to the dorsum of the finger to retain the general shape of the phalanx, and in one instance I was enabled to produce a more slightly tip of the finger in this way.

From the foregoing it will be seen that the prognosis is very grave as regards the fate of the phalanx unless an early operative interference is made. If, on the other hand, the periosteum is opened thoroughly at an early hour the finger-tip may be saved.

It is, perhaps, unnecessary to say that in attempting to classify these various affections I may have failed in making the definitions distinct; nevertheless, in actual practice the above classification has been of practical use to me. That these various affections run one into the other is equally true, and that at times it is impossible to make a clear distinction is true; but if by writing this paper I can throw any light on a more accurate understanding of the subject of felonies my object will have been accomplished.

It has not been uncommon for me to meet cases which have been ignorantly treated. To make an in-

cision down through the periosteum in a case of dermatitis is worse than useless; on the other hand, to fail to make an incision in a case of periosteitis or osteitis of the terminal phalanx at the earliest moment that the case comes to one is criminal negligence.

I have purposely omitted many little details of treatment in order to emphasize the importance of this differentiation of the various diseases which are known under the generic term of felon, and as a result of my personal experience I would suggest the following conclusions:

- (1) That the term "felon" be abolished.
- (2) That an anatomical classification of the inflammatory affections of the finger be adopted.
- (3) That in all cases of periosteitis or osteitis of the phalanx an immediate incision is imperative.
- (4) That in cases of suppurative theritis an anesthetic should be administered, and a careful incision made into the anatomical structures which are involved in the pathological process.

Clinical Department.

TWO CASES OF CORNEAL WOUND WITH PROLAPSE OF IRIS.

BY ALLEN GREENWOOD, M.D., WALTHAM, MASS.

The treatment of these two cases was put under my charge through the kindness of Dr. E. R. Cutler of Waltham.

CASE I. Was called in consultation February 27, 1891, to see J. G., a little girl of ten. About two hours previously she had been using a pair of scissors and accidentally stuck one of the scissor blades into her right eye. On examination the following conditions were found: In the outer margin of the cornea close to the sclera there was a perforating wound about one-eighth of an inch long and running parallel to the edge of the cornea. Caught between the edges of the wound was a bit of the free edge of the iris, it probably having been washed out by the escaping aqueous on the withdrawal of the blade. There was a little blood in the lower part of the anterior chamber. Chloroform was given, and by using a thin flat probe the protruding portion of iris was pushed back and smoothed out. The anterior layer of the iris had been slightly lacerated by the point of the blade. The pupil, which before had shown a V-shaped elongation to the wound, was again restored to nearly its original shape except for a slight nick at its outer edge.

As the prolapse showed no inclination to return, pilocarpine, in one-half per cent. solution was dropped in, and the eyes covered with absorbent cotton and bandaged.

February 28th. Bandage and cotton removed, but as there was no pain or discharge the dressing was re-applied without the lids being opened.

March 1st. Dressing removed, and the eye found in good condition. The corneal wound was healed, and the blood in the anterior chamber had disappeared. The iris showed no signs of inflammation; and the pupil was nearly perfect. Slight amount of photophobia. Pilocarpine was again used. Re-bandaged.

March 2d. Bandages removed for good, as the eye was in excellent condition, there being but little injection of the vessels near the wound. Pilocarpine used as before.

March 3d. The eye causes no trouble, and the pupil is perfectly round and responds normally to light and accommodation.

July 6, 1891. Examined to-day. Pupil normal, and the iris shows no evidence of ever having been injured. The scar being so close to the sclera does not show except on closest inspection. Vision perfect.

CASE II. Was called in consultation June 20, 1891, to see Louise G., a little girl of five, who had had a three-inch board-nail enter her right eye. The nail had been thrown from some height above her, and she had looked up just in time to have it enter the eye. She immediately pulled it out and I saw her about an hour after the injury. As she would not allow the eye to be inspected, chloroform was given, and the following conditions found: The small end of the nail had entered the eye in the lower left-hand quadrant of the cornea, slightly involving the ciliary region. There was a jagged hole in the cornea, about one-eighth of an inch long and one-sixteenth of an inch wide, through which a large piece of iris was protruding. This portion of iris was much lacerated, and had been torn from its attachment at the lower part, as though the nail had taken a direction downward and outward as well as toward the interior of the eye. The anterior chamber was empty, and owing to the position and size of the wound the prolapsed iris would not remain in place when returned. In the upper part of the iris there was quite an extensive ecchymosis. Attempts to replace the prolapsed iris failing, that portion was snipped off and the remaining edges placed inside the anterior chamber as far as possible. A few drops of serine sulphate were then dropped in and the eyes covered with absorbent cotton and bandaged.

The myotic was used, as was pilocarpine subsequently, to prevent the edges of the iris from entering the wound. The cotton and bandages were renewed every day for a week, and then discarded, as the wound had healed and the anterior chamber was again established.

For three weeks there was some photophobia and circumcorneal injection but no pain.

About four weeks after the injury the following conditions were present: A large irregular white scar in the lower left-hand quadrant of the cornea; shallow anterior chamber; and pupil nearly normal in size but drawn down to the scar, where the iris is attached.

Repeated instillations of atropine failed to dilate the pupil but slightly and since then the pupil has been steadily drawn down to the scar, in spite of mydrastics, until it is no larger than a pin's head. There have never been any symptoms of sympathetic trouble in the left eye.

January 5, 1892. Examined to-day. O. D. vision practically *nil*. The scar in the cornea, which extends from the sclera nearly two-thirds of the way to the centre, is not nearly as opaque as at last examination. In the lower part of the iris, exactly in the median line, there is a round opening, about one diameter across, showing through the corneal opacity. Just above and a little to the inside of this is the pupil, which is egg-shaped, about the size of a small pin's head, and having the portion of iris forming its lower point attached to the corneal scar. Except where the iris is attached to the cornea the anterior chamber has been preserved. That portion of lens which can be seen through the small pupil is white and glistening, showing that a traumatic cataract has formed.

Of course, with such an injury a very favorable result could not have been secured, but I think a much better pupil would have resulted if atropia had been used from the start. In regard to the appearance of the eye a better result was obtained than was expected, as the scar is becoming less opaque, and the pupil being so small renders the white lens less conspicuous.

From these two cases, particularly the second, I would draw the following conclusions:

In all cases of marginal wound of the cornea with protrusion of a portion of the iris, where the protruding iris can be successfully replaced, some myotic should be used.

In cases, however, where the protruding portion has to be snipped away and especially where the wound is large and lacerated, some mydriatic should be used from the start to secure ultimately as large a pupil as possible.

An exception might be taken to this last in cases where it was evident that the lens was injured, and where a small pupil would render the subsequent cataract less conspicuous; but then there is the objection, that if a cataract-extraction becomes necessary, from subsequent loss of the other eye, it would be apt to be less successful than if the pupil were large and the iris less adherent.

Of course, every case has to be treated on its own merits, and it would rarely happen that two cases would present exactly similar conditions; but the point I wish to emphasize is, that, in cases of marginal wound in the cornea, the rule of always using a myotic should not be too blindly followed, and I think the use of a myotic in my second case was a mistake, and that a better result would have been obtained by the use of atropia.

A NEW, SAFE AND SURE METHOD TO EXPEDITE DIFFICULT CASES OF LABOR.

BY MARSHALL L. BROWN, M.D., OF ALLSTON, MASS.

DR. PLAYFAIR, F.R.C.P., Professor of Obstetrics of King's College, London, writes recently of an "entirely modern oxytocic by manual pressure applied directly to the uterus to increase the force of feeble pains, etc."¹

It is something like ten years since I commenced the use of the herein-described method² of expediting difficult and retarded cases of labor with pelvic or breech presentations. I have made use of the same method in difficult labors with vertex presentations, since that time, when the presentation was a safe one, and, from any cause, the expulsive pains of the patient seemed inadequate for the delivery of the child.

I well remember the teachings of our professor in obstetrics, Dr. Dix Crosby, of Dartmouth College, who was pre-eminently a practical man, who said that having made out the presentation, as a general rule, we were to wait patiently; we were not to use the blunt hook; we were not to get our finger into the flexure of the joint, at the groin; but we were to wait; nature would eventually accomplish the delivery. I had had a few cases of labor with breech presentations and followed these eminently practical directions and all went well. In the following case they did not work as satisfactorily.

¹ Braithwaite's Retrospect, Part III, January, 1891, p. 200, first two paragraphs.

² Read before the Boston Gynecological Society, 1884.

Mrs. G., a closely-built, vigorous, young woman, weighing one hundred and thirty-five pounds, of sanguine temperament and florid complexion, was taken in her first labor in the afternoon. The night wore away — the following day, the next night, another day, to the third night. Up to this time, everything being natural, the parts cool and moist, the presentation having been early made out, we had kept her courage and hope sustained by telling her that as long as she remained cool, the pulse and temperature natural, the parts moist, there was no cause for anxiety or alarm, and that all would eventually come out right. During the evening the pains increased in strength and duration. The patient became excited at the delay, and called for ether and the instruments, and later in the night begged piteously for them. I finally gave her ether at the commencement of each pain, and while it continued. While giving the ether, in her writhing, she got crosswise on the bed, with her head towards the wall. I gave the towel cone, by means of which the ether was given, to the nurse, and, placing my hands well spread out over the fundus of the womb, I applied a gentle and continuous force in downward and backward pressure, while the pains were on, upon the womb and contents, in the line of the axis of the pelvis. When the pains ceased I stopped the pressure. As the patient made no complaint, I continued applying the force, gradually increasing it at each pain. After an hour or so, on making examination, I found that she was making progress, and the breech was engaging. I continued the application of this force; and after about three hours more of hard labor, on the part of the patient and myself, I had the satisfaction of knowing that the labor would terminate successfully. Meanwhile, however, the husband and friends had become panic-stricken (in spite of my assuring them that all was going on well) and desired counsel. I assented. While the husband was after the counsel, I gradually increased the force applied, until it was all I was capable of exerting with my hands, as before described, upon the abdomen of the patient.

After the breech had passed the upper strait, she made more rapid progress; and at the proper time, when the breech began to be delivered, I passed to the other side of the bed and rendered the necessary assistance and delivered her safely of an eleven pound girl, before the return of the husband with the counsel.

As this was the first time of my applying force in this manner, I felt not a little anxious as to the result although I had reasoned, that, if the force was properly applied, and in the right direction, no harm could be done to the patient. I have to say, however, that she did not complain of any unusual tenderness of the abdomen, and she made as quick and perfect a recovery as any patient I ever had.

I searched the authorities for any description of the application of force applied in this manner, to expedite labor, and have thus far failed to find any mention or hint, of its ever having been before so applied.

From that time to the present, I have made use of this method, and have at times applied so much force as to be apprehensive lest some harm might come to the patient; but in every instance the patients have made speedy and perfectly satisfactory recoveries. From the experience I have had in the use of this method, I am satisfied that it is a safe, sure and satisfactory help in the delivery of difficult and retarded

cases of labor, with either breech or vertex presentations.

Briefly, the method consists in applying a force synchronously with the natural labor pains, by and through the hands of the obstetrician, so spread as to embrace as large a portion of the fundus of the womb, as may be possible, and applied downwards and backwards in the direction of the axis of the pelvis.

The following are directions which should be remembered and followed in making use of this method:

(1) As to the position of the patient. It can best be made use of when the patient is crosswise on the bed, in nearly the same position as when the forceps are to be applied.

(2) The hands of the obstetrician should be so spread as to embrace as large a portion of the fundus of the womb as possible.

(3) The force should be applied when the pain commences, gently at first, gradually increasing it to the end of the pain and should cease with the pain.

(4) The force must be applied downwards and backwards in the direction of the axis of the pelvis.

Finally, certain precautions should be borne in mind in the use of this method:

(1) It should not be used unless the presentation is a safe or deliverable one.

(2) It should not be applied spasmodically by jerks, but with a gentle, gradually increasing pressure.

(3) It should not be used unless the os uteri is dilated or dilatable.

Following the above directions, and bearing in mind the cautions given, this method will, I am sure, be found of great value in difficult and retarded cases of labor, and for the average general practitioner, safer than the forceps.

A CASE OF QUADRANT-ANOPSIA WITH RIGHT SENSORY AND MOTOR HEMIPLAGIA.¹

BY J. J. PUTNAM, M.D.

A YOUNG man, eight years ago, fell on the ice, striking on the left temple. He has a depression in that neighborhood which I suppose may be the result of this fall, although on the other side of the head is an equally marked depression which is unaccounted for. At any rate he had a severe fall and was unconscious after it for two weeks. This was followed by severe headaches from which he suffered very much. They were not localized in the neighborhood of the injury, but were rather diffuse and especially felt in the frontal region. Two years ago, while taking his bath, he had suddenly a strange sensation come over him, felt his right hand suddenly numb. He became almost unconscious. It is a little doubtful whether he had a convulsion or not, but he became hemiplegic on the right side. This lasted only a limited time, about two weeks, and passed away, and at that time he ceased to be troubled with the headaches which had followed him until then. After this he worked steadily until last April, when he again became hemiplegic on the right side. He came to me first a few days ago. He has now partially recovered from his hemiplegia, but improves slowly.

The physical examination shows that this is a well-marked case of sensory hemiplegia, to begin with. The patient is unable to notice differences in tempera-

ture on the right side, and also his sense of position is almost abolished, so that with the eyes shut he is unconscious in what position his fingers or toes or foot or hand are placed. The sense of touch is pretty much abolished.

Not only has he a sensory hemiplegia, but he has a peculiar difficulty in his field of vision, the right lower quadrant being lost out of both fields. There is not complete hemianopsia, which is more common, but loss of a quadrant, which is, so far as I know, quite uncommon. When hemianopsia is due to a lesion in the internal capsule in the neighborhood of the optic thalamus there is generally, as in this case, sensory hemiplegia; but, so far as I know, no case has been reported in which a quadrant was cut out in both eyes from lesion in the capsule. Possibly this lesion took place at the time of the first attack, and he may have had a series of softenings in different parts of the brain. Dr. Seguin considers the cuneus as the probable centre of vision and quotes Dr. Hun's case to show that a lesion involving the lower portion of the cuneus may account for a quadrantic defect. If the pathology of this case is what it seems to be, that is, if the same lesion causes the hemianesthesia and the loss of the quadrant, it would seem as if the optic radiations through the brain must be divisible into two parts just as the cuneus is.

The hemiplegia although well marked is not severe. He can extend his hand, although with some difficulty. With the eyes closed he has marked ataxic movements of the hand. It is interesting to note that the face is affected to a relatively considerable degree. The nasolabial fold is markedly less on the right side than on the other. That is interesting because the fibres for the facial nerve are thought to run quite far forward relatively to the other tracts in the internal capsule. The heart in this case is not diseased.

UNFAVORABLE SECONDARY EFFECTS OF SULPHONAL.

BY JOHN H. GRANT, M.D.,
Hospital Steward, United States Army, Plattsburgh Barracks, N. Y.

RECENTLY, I attended two cases of epidemic influenza (thoracic-nervous), one, a married lady of slight physique, who, after a week's illness, considered herself convalescent, but still suffering from sleeplessness — no sleep for forty-eight hours; sulphonal-Bayer, one scruple in four ounces of hot water, was given at bedtime, which, within a few minutes, caused profuse perspiration and, apparently, a profound sleep. Next morning the patient awakened to find herself unrefreshed and completely prostrated, muscles of the arms and legs flaccid, and unable to turn in bed (voluntary effort wanting) without help. In addition she complained of great constriction of the head and pain, as if, the patient expressed it, "a corkscrew had been inserted" at the vertex. For some days the patient, owing to the muscular weakness, was obliged to remain in bed; in fact, suffered a relapse of the influenza, although not having at any time left her room since first attacked.

The day following Case No. 1, the writer was called to attend a gentleman of middle age, who appeared to be convalescent from an attack of epidemic influenza — an excited imagination and inability to sleep were the subjective symptoms presented. Sulphonal-Bayer,

¹ Read before the Boston Society for Medical Observation, November 2, 1891.

one scruple dissolved in hot water at bedtime, was given, as in the previous case, and with the same immediate action. On calling the next morning the gentleman was found greatly prostrated, hardly able to move a limb, and with the symptoms of constriction and "corkscrew" pain at the vertex, exactly coinciding with the history given in the first case. A relapse of some severity followed, lasting nearly two weeks. In both cases a rapid, but weak and compressible pulse, was noted on the morning following the sulphonal. The sulphonal was preferred as a hypnotic agent because of the supposed "total absence of any injurious effect on the heart," even after continued use. That sulphonal, like all the other recent remedies obtained through the coal-tar series, has a depressant action on muscular structures (the heart included) is inferred; and its use contraindicated in all cases of prostration of the vital forces.

Medical Progress.

RECENT PROGRESS IN THE PATHOLOGY OF THE NERVOUS SYSTEM.

BY PHILIP COOMBS KNAPP, A.M., M.D.

(Concluded from No. 4, page 90.)

TABES DORSALIS.

ERB¹⁵ has recently studied a large number of cases of tabes with reference to the etiology, criticising the report of the German army surgeons, who found only 7.4 per cent. of syphilis in soldiers suffering from tabes. He found that 49 out of 51 officers with tabes had previously had syphilis. Out of 300 patients of the better class, who could naturally give more accurate information, in 33 there was no apparent syphilitic infection; in 267, or 89 per cent., there was infection, 190 having had secondary syphilis and 77 a chancre only. Of the 33 non-syphilitic cases, 19 had suspicious symptoms, and 24 had gonorrhoea. In 12.3 per cent. tabes developed in from one to five years after infection, in 37 per cent. in 6-10 years, in 24.7 per cent. in 11-15 years, in 14.2 per cent. in 16-20, in 4.8 per cent. in 21-25 years, in 1.9 per cent. in 26-30 years, and in 0.7 per cent. in 30-35 years. Out of 5,500 other patients, men from the upper classes, 22.5 per cent. had syphilis. The proportion for women with tabes was about the same as for men. Few, except those who have had syphilis, run the risk of having tabes. Out of 281 cases, in 27 per cent., syphilis was the only cause; in 11 per cent. it was associated with exposure to cold, in 6 per cent. with overwork, in 9.5 per cent. with sexual excess, in 5 per cent. with injuries, in 12 per cent. with neurotic heredity, in 13.5 per cent. with exposure and overwork, in 1.7 with exposure and sexual excess, in 7 per cent. with overwork and sexual excess, and in 4 per cent. with more than three of these factors. In the non-syphilitic cases exposure and sexual excess seemed to be most important factors. In only two cases was there direct heredity, and in only 28 per cent. was there a neurotic taint. Sexual excess seems of some importance, being present in 15.8 per cent. Merchants and officers seemed most commonly affected, probably due to the fact that they are more frequently affected with

syphilis. Although syphilis is the most frequent cause of tabes, tabes does not indicate necessarily a previous syphilis, for many cases of tabes are on record where no evidence of acquired or hereditary syphilis can be obtained.

Minor¹⁶ has recently studied the question of the cause of paraparesis in tabes dorsalis, especially the cause of transitory hemiplegia and paraplegia in the affection. He bases his study upon the case of a young woman who, five years after an attack of syphilis, had paraplegia, with other symptoms of meningo-myelitis. During the paraplegia there was no rigidity, and the knee-jerks were absent; there was also paraparesis of one abductus, contraction of the pupils, Argyll Robertson's symptom, and anesthesia. Soon after shooting pains developed. The paraplegia yielded to anti-syphilitic treatment, but the patient remained with the classical symptoms of tabes. A year later she had severe headache, which also yielded to anti-syphilitic treatment, but it returned in three months, and, although again relieved by treatment, right hemiplegia and aphasia followed, and the patient died a month later. The autopsy showed typical degeneration of the posterior columns. In the cervical portion of the cord there were lepto-meningitis and three myelitic foci in the lateral columns, the thickened membranes containing many vessels with thickened walls filled with leucocytes. Characteristic syphilitic endarteritis was found in the cerebral vessels, with thrombosis in the basilar artery and softening in the left hemisphere. From a study of this case and of the literature, Minor dissent from the view that hemiplegia and paraplegia may be special tabetic symptoms; at least, he regards it as an open question. It seems to him most probable that in the majority of cases, as in his own, hemiplegia and paraplegia are symptoms of ordinary syphilis of the brain and cord, sometimes combined with degeneration of the posterior columns, which, in its turn, is dependent upon syphilis. He doubts if there be any true tabetic paraparesis, but he is disposed to believe that all paralyses in tabes, including a part, at least, of the oculo-motor paralyses, are merely symptoms of syphilis of the cerebral nervous system.

Goldscheider,¹⁷ reporting a case of tabes with marked weakness of the legs and moderate muscular atrophy, where the autopsy showed, beside degeneration of the posterior columns, limited degeneration of the left lateral tract, softening in the left lenticular nucleus, and degeneration of the nerves, considers again the question of the origin of paralysis and atrophy in cases of tabes. After a careful review of reported cases he recognizes, with Déjerine, that, although paralysis and atrophy are due in some cases to affections of the lateral tract and anterior cornua, in others sensory and motor symptoms depend upon peripheral neuritis.

Since Westphal some years ago maintained that, if in disease of the cord, the columns of Burdach at the junction of the dorsal and lumbar portion were involved, the knee-jerks were lost, but that if this region were intact, they were still present, it has been supposed that, in degeneration of the posterior columns affecting only the upper portions of the cord, the knee-jerks were preserved. Eichhorst¹⁸ reports the case of a woman brought to the hospital unconscious with right hemiplegia. As the knee-jerks were absent, tabes was

¹⁵ Zietsehr. f. klin. Med., xix, 401, 1891.

¹⁶ Loc. cit., xix, 444, 1891.

¹⁷ Archiv f. pathol. Anatomie und Physiologie und f. klin. Med., xxv, 25, 1891.

suspected. The autopsy showed, beside the lesion giving rise to hemiplegia, complete degeneration of the posterior columns in the cervical and the upper two-thirds of the dorsal region. Westphal's zone, however, was intact. Further examination revealed extensive neuritis in both crural nerves, showing, therefore, that in cervical tabes the knee-jerks may be absent from coexisting neuritis.

Raymond¹⁹ throws some doubt upon Westphal's position. In a case of tabes of two years' duration, beginning with paralysis of the fourth cranial nerve and followed by thoracic crises, with hyperesthetic areas, pains and muscular weakness in the legs and absence of knee-jerks, the autopsy showed that the lumbar segment of the cord was intact, and that the peripheral nerves were normal. No special mention, however, is made of the crural nerves. The interest of Raymond's case lies in the distribution of the lesion in the posterior columns, and this case is compared with the other autopsies of early cases of tabes. From these cases he finds that, although the location of the lesion is not always absolutely identical, the alterations always involve the centre of the posterior columns, in the form of a sclerosis which lessens from front to back, and which, at first, does not reach the outer edge of the cord. It is always separated from the gray matter by a zone of intact white matter, and, almost always, it involves exclusively the column of Burdach, affecting the column of Goll to a lesser degree if at all. Almost always, independently of this zone of sclerosis, there has been found at some level in the cord a smaller zone of sclerosis contiguous to the posterior median fissure in its anterior portions. In several cases the integrity of the peripheral nerves and the membranes have been confirmed. The regions first involved in tabes are those portions of the median radicular zone which have been found by Flechsig to be synchronous in development and to be the earliest developed in fetal life. The regions which develop later are involved later in the sclerosis. True tabes is therefore a systemic affection of the central nervous system, and is independent of any change in the nerves or the meninges.

EXOPHTHALMIC GOITRE.

Möbius²⁰ gives an excellent digest of recent investigations in the pathology and treatment of this affection. The exophthalmos may, at the outset be unilateral. Stellwag's sign,—an unusual magnitude of the palpebral fissure and infrequent winking—is a symptom of irritation of the muscles that open the eye. Gräfe's sign, however, is present occasionally in other affections and is by no means constant in this affection. Insufficiency of convergence is not uncommon, and it is attended with no diplopia, but with merely a feeling of tension. Paralyses of individual muscles of the eye are not very uncommon. Tremor of the eyelids and nystagmus have been noted in a few cases. The cardiac symptoms are among the earliest observed. Beside the familiar rapid pulse, irregularity, arterial pulsation, palpitation, and angina pectoris may occur, and cardiac murmurs are not uncommon. Goitre is seldom absent, and it usually first affects the lateral portions of the gland. In a few cases of goitre due to other causes the symptoms of this special disease have developed. The resistance of the skin to the electric

current is diminished in the majority of cases, due probably to the increased sweating, but a normal resistance does not invalidate the diagnosis, and it is sometimes present in other conditions. Pigmentation of the skin is occasionally seen, under the forms of vitiligo, bronzing, reddening and pigment spots, which are in rare cases seen in the mucous membranes. Increased sweating, loss of hair, and oedema are also noted. The respiration is often increased, cough is not unusual, and the expansion of the chest is below normal. Digestive disturbances are very common; diarrhoea is most frequently seen, usually of a paroxysmal character; vomiting, icterus, and intestinal atony are also noted. Amenorrhoea is a common symptom. Beside the subjective feeling of increased heat a definite and persistent elevation of temperature may occur. The chief nervous symptoms are a fine tremor (8-9 vibrations a second) one of the most constant signs of the disease; paraparesis, with giving way of the legs, cramps, muscular atrophy, and mental disturbances, varying from irritability, restlessness, and depression to pronounced delusional states. Among the complications are epilepsy, hysteria, paralysis agitans, diabetes, polyuria, tabes, myxedema and syringo-myelia. Rapid pulse and goitre never fail, exophthalmos is almost always constant, and among the other most constant signs are pallor, emaciation, tremor, Stellwag's sign, and increased moisture of the skin. The great majority of patients are women in middle life, and the neurotic taint is an important factor. The course is very variable; a few cases recover, and death is usually due to the cardiac complications. The old hypothesis that the affection is due to disease of the sympathetic must be abandoned in view of recent autopsies. Changes, which Möbius regards as inconclusive, have been found in the medulla; and in a few instances the thymus gland persisted. In England iron, arsenic, and belladonna have met with the most favor in treatment. Digitalis and iodine are not only useless but injurious. Möbius himself has found most help from bromides. Electricity usually gives some relief; generally in the form of galvanism, but of late faradism has proved beneficial in the hands of several observers. Baths, gymnastics, water-cures, and high altitudes have proved beneficial. In several instances treatment of nasal disturbances has given relief. In a number of cases, reported by various observers, very pronounced relief seems to have followed removal of the thyroid, and Lemke, who has operated successfully in two cases, says boldly, "Patients with exophthalmic goitre do not belong in the medical but in the surgical wards." Rest and the avoidance of accidents is imperative. Möbius rejects the theory of disease of the sympathetic or disease of the medulla, and he is not disposed to regard exophthalmic goitre as a neurosis, in the sense that hysteria and epilepsy are neuroses. The proximate cause of the disease is probably a morbidly increased activity of the thyroid gland. This hypothesis is supported by the similarity and points of contrast between exophthalmic goitre and other affections due to a diminished activity of the gland, cachexia strumipriva, myxedema, and cretinism; by the fact that exophthalmic goitre not infrequently develops in old cases of goitre, and by the fact that operative treatment of the goitre sometimes has a material influence upon the disease. As to the cause of the primary disease of the thyroid we know as yet nothing, but it may possibly be due to some poison.

CEREBRAL HEMORRHAGE AND SOFTENING.

Dana²¹ has made an elaborate study of 74 autopsies of cases of cerebral hemorrhage and acute softening; 50 cases were hemorrhage, 12 embolism, and 12 thrombosis, 14 of the hemorrhages were meningeal, 32 affected the central ganglia, 23 of these becoming ventricular. Contrary to the usually accepted rule, two-thirds of the cases of embolism affected the arteries on the right side. In regard to the duration of life after a shock, he finds that if the hemorrhage be ventricular the patient is likely to die in from one to three days, if cortical or central, in a week. After a week the patient is likely to live. In his cases hemorrhage was commonest between the ages of thirty and fifty, contrary to foreign statistics, which leads him to speculate as to whether apoplexy may not occur at an earlier age in Americans. He gives the following table for differential diagnosis.

HEMORRHAGE.	SOFTENING.
Between thirty and fifty. Hereditary history of arterial disease.	Early or later age.
Sudden onset with coma and paralysis occurring together, the coma deepening.	Premotor symptoms and more gradual onset, or more transitory coma.
Initial and early rigidity.	Presence of weak heart or endocarditis.
Very unequal pupils.	Slight hemiplegia with anesthesia.
Stertorous breathing and hard, rapid, strong pulse.	Puerperal state.
When convulsions exist, peculiar conjugate deviation, the eyes turning first to one side and then to the other.	
Early rigidity.	
Convulsions.	
Temperature subnormal at first, rising rapidly if case be likely to prove fatal, and temperature higher on paralyzed side.	

REACTION OF DEGENERATION.

Starr and Young²² have made some elaborate electrical researches upon electrical reactions in degenerated muscles. Mr. Young is a practical electrician, suffering from acute anterior poliomyelitis. The reason why degenerated muscles do not respond to the interrupted current is because the current is of too short a duration. An apparatus was devised by which voltaic alternatives could be applied to the muscles, and by a commutator run by an electric motor any number of revolutions could be made. These revolutions were recorded on a chronograph. Starting at a low rate of speed it was found that the muscles responded separately to each reversal of the current. At a higher rate of speed the muscle became permanently contracted, the contraction increasing with the speed up to a certain point, when it began to relax, until finally, with a high rate of speed, no contraction could be obtained. That this failure to contract is not due to fatigue is shown by the fact that, when the speed is diminished, the muscle again contracts. The rate of alternation at which the muscle ceases to respond to a given current is called the critical rate. This critical rate was observed to become higher as the patient improved, and to be higher on the days when he felt vigorous, and these variations in the critical rate are regarded as having a distinct prognostic value. Furthermore under arsenic and strichnine the critical rate was observed to increase for about ten days, and after that to remain stationary or to decline. These tests, therefore, indicate that in giving these drugs in diseases of the cord it is better to give them for ten days,

and then to stop them for ten days; resuming again in like manner. In this way the best results are obtained.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

G. G. BEARS, M.D., SECRETARY.

REGULAR Meeting, Monday, November 14, 1891, the President, DR. FREDERICK I. KNIGHT, in the chair.

DR. J. C. WHITE read a paper on
SOME DANGERS OF INFECTION INCIDENTAL TO PROFESSIONAL LIFE.¹

DR. EDWARD WIGGLESWORTH: The value and importance of Dr. White's remarks are self-evident. I wish to say one or two things in corroboration of what he has said. As to the animal parasites, I wonder whether it has occurred to physicians how commonly they are disseminated by horse-cars. I have had quite a number of cases of pediculi capitis the source of which could be traced pretty directly to horse-cars.

With regard to scabies. It is evident that scabies is increasing in a very marked way owing to immigration and to the massing together of our poorer population in tenement houses. Twenty years ago one might not see a case of scabies from one year's end to another, whereas now we have perhaps three to six cases a day in a clinic. It seems as if we were getting into a condition of things in which it was necessary for our hospitals to adopt the same plans as they do in Germany, and more particularly at the hospitals in Paris, for an immediate cure, by a practical flogging of the patient to such an extent as to get down to the neighborhood of the animal, then applying to the skin one strong inunction of something sufficient to kill the insect, regardless of the subsequent dermatitis of traumatic nature thereby occasioned and which will pass away subsequently under almost any or no treatment. We should have, I think, attached to our hospitals, baths for the treatment of scabies in this manner if we would make any headway against the disease.

Dr. White spoke of cases of dissemination of syphilis by midwives. There was one case that some twelve years ago fell under my own notice where I think seventeen people were infected by a midwife from Nova Scotia, who then returned to Nova Scotia for fear of the consequences of what she had done. I wrote to Nova Scotia to one or two of the men who had been in the school at the same time I was, and they reported her arrival there and the fact that several women had been infected by her before the disease was recognized. That merely adds one more to the cases to which Dr. White has alluded.

Now it seems to me the most important question at the present time is in regard to the establishment of syphilitic hospitals, or, at least, wards in the general hospitals. As Dr. White has shown us, leprosy has diminished markedly simply by segregation. If segregation can work that effect in the case of leprosy, how much more would it produce it in the case of syphilis, where the lesions are very numerous, often masked and so neglected by the possessors of them. It

²¹ New York Medical Record, July 25, 1891.²² American Journal of the Medical Sciences, October, 1891.¹ See page 105 of the Journal.

is a disease which is being daily disseminated through the community. I recently saw a case from kissing, where there was no reason to doubt the man had done anything else than to kiss. I saw a case two or three days ago on the finger, and if one chooses to look back through one's books there is no end of such instances. It makes no difference what part of the body is exposed; where there is a possibility of the entrance of the virus, there the virus, if allowed to stay long enough, is going to enter with all its lamentable consequences. Under all these conditions, with the fact patent that the disease is so easily communicable, is communicated to innocent wives and children, and knowing that the spread of syphilis must have already attained a very great degree in extent, if we are ever going to try to stop it, it seems to me we ought to begin in the most thorough way, and to try to have wards established in the general hospitals. I think there is nothing more important for the whole profession at the present time than to try to get such hospitals or wards established.

DR. AUSTIN PETERS: I suppose, as a veterinary surgeon, the diseases transmissible from animals to man are those which particularly interest us. The reader mentions ringworm, glanders, anthrax, actinomycosis and tuberculosis. Two diseases transmissible, one from animals to man, and the other possibly transmitted in making post-mortems, not mentioned, are rabies and tetanus. The ringworm I think he did not mention so much as being transmissible from animals to man. I know a woman who a year ago had a cat which had ringworm and transmitted it to its offspring. That lady gave the kittens away and every person who had one of these kittens had ringworm appear in one or more of the family.

As regards glanders, we have more or less in Massachusetts. I suppose I see two or three glandered horses a year, and, of course, it is a very dangerous disease. I always make a practice of carrying a lot of corrosive sublimate tablets and wash my hands in a solution of 1 to 100 as soon as I am through examining one of these horses. Anthrax, I think, is very rare among cattle in Massachusetts. I have never seen a case. The only case of anthrax I ever saw was with Dr. Ernst at the Massachusetts General Hospital. We saw a man with malignant pustule. I think the man worked in a tannery and carried hides on his shoulders, and his neck had been scraped with the edge of a hide and in that way he became inoculated. His neck and shoulder and left arm were tremendously swollen.

Rabies among dogs has been very prevalent the last year and a half or two years, but in many of the cases the dogs do not have a propensity to bite. Only a small per cent. of them have the violent form. Most of them have dumb rabies, become paralyzed, and die without doing harm; and consequently little attention is paid to them. Last summer I saw a man who had been bitten by a dog that had rabies. I asked Dr. Ernst's advice as to whether the man had better be induced to go to the Pasteur Institute in New York. Dr. Ernst advised it, and the man went. This was last July; the man is alive and well. Another case was where a small child was bitten by an old dog whose teeth were very dull and did not break the skin. Dr. Ernst was consulted about the case, but thought, as the skin was not broken, that there was no danger to the child. That was a year ago last summer, and the child is well to-day.

In reference to tetanus. A few years ago a young veterinary surgeon made a post-mortem on a horse that died of tetanus in Needham; he himself died of tetanus soon after, and the daily papers at that time said he inoculated himself by making a post-mortem on a horse that died of this disease. At that time tetanus was not recognized as a disease due to a bacillus, and the newspaper story was laughed at; but present knowledge would seem to indicate that it was possible.

Actinomycosis we see occasionally, but I do not think it is particularly transmissible from animals to man. It is very common in the West, particularly in Illinois.

Tuberculosis is of more interest to us all, because we see so many cases among dairy cattle, and because cows with general tuberculosis or tuberculosis of the udder can undoubtedly give the bacillus in the milk, and in that way they might infect a susceptible person or a child who is drinking a good deal of milk.

DR. H. C. ERNST: There is one point I should like to emphasize in carrying out Dr. White's suggestion in regard to prophylaxis. He has spoken of the care the physician should exercise in washing his hands after each examination. I should like to add the caution that, so far as I know, is very little attended to, and that is that the physician should never use the same towel twice. I think there should be a very large supply of small towels, that they should never be used but once and then be thrown away and thoroughly steamed before being again employed.

The whole question is of great interest, and I think the fear of transmission of disease to the physician is perhaps more emphasized to one engaged in work like that done at my laboratory. It appears to me work of that kind gives one a certain sense of security because, I think, one realizes the best methods to handle it. From a general point of view it seems to me that Dr. White has emphasized those points very perfectly indeed.

DR. ALEXANDER BURR: Holding the position of inspector at the Brighton abattoir, I have seen the dangers to which many of the butchers were exposed. I think the general practitioner who is located away from the abattoir has the impression that most of the butchers have nothing but healthy animals to deal with, whereas one who has seen what they are at times called upon to dress, is surprised that there are not more cases of fatal nature due to dressing of the animals. Of the animals that come to the Watertown stock-yard, some arrive dead and some almost ready to die. Those that are dead are carted down to the dead-house, and those with any semblance of life left are generally carted to the slaughter-house to be dressed, and such as seem likely to die before the wagon reaches there, are generally shot and bled, and allowed to remain until the wagon arrives. There are, it seems to me, a great variety of infectious diseases which these men are called upon to handle.

In the case of anthrax, one of the most virulent of bovine diseases, during 1890 we had nine cases, five of which arrived there dead, and four which arrived at the yards showing symptoms of the disease. The first five were sent at once to the dead-house, and we made inoculation experiments from the blood of one of these animals upon two guinea-pigs, which died within two days. I remember going into the slaughterhouse after one of the other four was drawn in, and

when they get to the point where they hang the animal up preparatory to taking off the hide and withdrawing the intestines and abdominal organs, I was struck with the peculiar discoloration of the omentum. Upon looking at the spleen I found that that was considerably enlarged and of a black, soft, tarry nature. I was rather suspicious of anthrax at the time, and ordered the animal thrown away, the floors washed, and instructed the men to at once wash themselves. This seemed rather surprising to them as they had not been accustomed to wash themselves after such a case. This will probably recall to you the case of anthrax that occurred some years ago and proved fatal. They dressed one of these animals that was brought in the wagon, and, as was their habit after washing an animal down, they run a cloth across the neck. This man had a scratch about the face. In the course of twenty-four hours he had considerable enlargement of that side of the face and glands, and showed symptoms of restlessness, vomiting, etc., and died in great agony at the end of four days.

Actinomycosis, I find, is quite a common disease there. I have seen thus far this year ninety-nine cases of it. I have never seen any ill effects from the dressing of such animals.

At the Massachusetts Veterinary College there have been one or two outbreaks of variola equina, and in each case the students have had more or less symptoms of it in the hands from the handling of the animals. One common trouble at the abattoir is from rupture of the intestines and bladder, setting up peritonitis. It is surprising how these men will handle these animals. They seem to think there is no danger whatever.

DR. ARNER POST: There is only one thing I wish to say and that is in regard to one of the dangers from syphilis. Physicians, as a rule, have some idea of the precautions to be taken in handling a case of syphilis which they recognize as syphilis, but a good many of the inoculations among physicians occur from cases which are not recognized. They are cases either in persons whom the doctor feels sure cannot have syphilis, or still more likely in cases of syphilis of non-venerous origin. It is not safe at the present day, when syphilis is so widespread, to suppose that any person cannot have syphilis, or that any class of patients is exempt from the disease. The number of cases of accidental or non-venerous syphilis is increasing very largely, it seems to me, at least I see very many more such cases, and Dr. Wigglesworth speaks of the number of cases that have accumulated on his books. I have seen in the last fortnight at least six cases in which the syphilis was non-venerous in character. The danger from these cases is greater before the diagnosis is made. I recall very distinctly one case in which a physician inoculated himself in caring for a poor woman who had been accidentally inoculated. Her primary sore presented a curious question of diagnosis for a little while, and this physician seemed to have no idea that there could possibly be anything from which he could be injured, until the mischief was done.

Physicians ought to regard with suspicion any sore on themselves which is chronic and which fails to heal and which they do not understand. They ought to be equally suspicious of simple sores on their patients, and ought to be careful of bringing their fingers in contact with such sores.

Dr. White's caution that the physician should wash

his hands after the patient visits him, even if he has not handled him, is a good one, I think. Many of these persons take pains to handle things within their reach, for instance, the doctor's books and chattels. It is a matter of surprise to me that physicians are not inoculated more frequently than they are.

DR. J. T. BOWEN: I have not had much experience with infection among professional men, but I should like to add my testimony as to the large number of extragenital chancrea that are found in syphilis. During the last three weeks I have seen three cases of extragenital chancrea in my office, and in two of them I feel quite certain the disease was acquired innocently. One of these patients was a trained nurse.

The only other point I had in mind which perhaps is not so directly connected with the subject as it might be, is as to scabies. It seems to me we cannot insist too much upon the importance of the recognition of scabies. I feel sure there is no other important skin disease in which physicians fail in a larger proportion of the cases to recognize the nature of the trouble. I have seen many cases of scabies treated by half-a-dozen different men without suspicion of the cause, where the diagnosis was not a hard one to one who had seen several cases.

DR. W. C. B. FIFIELD: A case was published in a recent number of the London *Lancet*, of anthrax treated by ipecac, and if the case as given in the London *Lancet* can be followed by others, it would seem we have reduced the treatment of malignant pustule to a very simple matter indeed. I notice that in one of the London hospitals, I think Guy's, a horse slaughterer was admitted to the wards with malignant pustule somewhere near the eyelid. Relying on statements made by some scientists that ipecac was fatal to the bacillus of malignant pustule, the surgeon cut away a part of this malignant pustule then carefully sprinkled it with powdered ipecac, and continued so to sprinkle it, and together with this he administered every two or three hours to the patient, powdered ipecac guarded by a little morphia, and the result proved entirely successful. I say if this can be followed up by others, it is certainly a wonderful advance over anything we have known as to the treatment of malignant pustule, it being almost always, I think, fatal.

In regard to the non-recognition of scabies by practitioners, I confess that I think I have seen a good deal of skin disease in the course of my life, and I do not feel quite as sure as I did a good many years ago in my diagnosis. When I was at the St. Louis Hospital I used to be appointed to keep the bell-rope over my shoulder for the admittance of patients, and at that time I was very apt, indeed, to make a diagnosis by finding the burrow of the scabies insect. In those days we used to mark them out with ink, but cases that have come before me in this country do not present the burrow as often as those did, and I cannot find anything to ink. The scabies I see here seems to me somewhat different from what I saw in Paris years and years ago.

DR. J. C. WARREN: I think surgeons feel the importance more now of precautions against contagion than they used to five or ten years ago. I think the younger men show great care in dealing with contagious disease. The precautions are greater with each successive year now that we understand what contagion really means in disease, and now that many of the younger practitioners have had training in the

bacteriological laboratory. Nevertheless, I find it requires all the circumspection which I possess to avoid contagion. I was one of those surgeons Dr. White alluded to as having contracted surgical tuberculosis. The diagnosis was not established microscopically, yet I had a little spot of anatomical tubercle on the dorsum of the thumb for some eight months, which I suppose was contracted from a case of tuberculosis of the hip-joint where I performed amputation and afterwards trephining of the acetabulum, and where probably I scraped the thumb with diseased bone, though at that time I was not conscious of having contracted any trauma at that spot.

I also felt somewhat disturbed last winter after dealing with a case of hydrophobia. A case entered the hospital and it was decided to try the treatment by very active bleeding, and blood was drawn from the radial artery one evening and from the vein the next day. I had one or two scratches on my fingers of the other hand and although I took precautions to cover them with collodion before the operation, there was one finger where the scratches were exposed, and blood trickled over that spot during fifteen or twenty minutes while the operation was going on. Some of the blood was taken to the bacteriological laboratory and inoculated into animals, with negative results, which was a comforting reassurance to me, and the statement was made in the laboratory that during the preparation of the cords of animals dead of hydrophobia, some of the broth thus prepared was occasionally smeared accidentally in the scratches of hands and with ordinary precautions no evil results had followed.

I should like to ask Dr. Jackson a question about a culture of tetanus bacilli which he had in his laboratory, and which he was inclined to think was dangerous if exposed by breaking of the tube. I would like to ask whether any experience in the laboratory has shown that the tetanus bacillus is more virulent when in the state of active culture than when in its ordinary state, as in dust.

DR. HENRY JACKSON: I don't know as that question can be answered to-day. Mice and guinea-pigs died very rapidly when injected with the bacillus of which Dr. Warren speaks, but they may also be very easily killed by injections under the skin of ordinary garden earth and of manure. It seems to me that human beings cannot be as susceptible to the disease tetanus as are these lower animals, since if such were the case tetanus would be infinitely more common than it is. Slight abrasions of the skin constantly come in contact with garden earth, not only in gardeners and people of that kind, but in people of every class and degree. I should feel that the culture ought to be kept very carefully as we do not know whether it has increased virulent power when grown on a suitable medium. Such a condition does occur in other forms of bacteria, as for instance, the tubercle bacillus. That bacillus when grown in favorable media is much more virulent than when grown in unfavorable media. Also anthrax; so it is perfectly possible that the tetanus bacillus may just be able to exist in the garden soil, and retain its vitality, but become much more virulent when grown in a medium which is suitable for its development.

DR. WARREN: The reason I asked was, that I felt great responsibility in passing around the test-tube to the class.

DR. RICHARDSON: There is one source of disease in hospital wards in the summer-time which is never considered; I refer to the danger of infection by flies. It is very difficult, if not impossible, to keep flies out. Whenever a wound is exposed, especially if it is a foul one, two or three flies will at once alight upon it. It seems to me quite as reasonable that insects should carry the germs of disease from patient to patient as pollen from flower to flower. The remedy—screens—is very expensive and quite ineffectual.

In the Massachusetts General Hospital great care is taken that there shall be plenty of towels, and no surgeon there ever uses a towel a second time. Five thousand go through the laundry every week.

There is little if any danger of hand infection to-day in the dissecting-room. It is extremely rare to see any trouble of this sort in the anatomical department. I think this is because the subjects are better disinfected than formerly. I have repeatedly wounded myself in the past seventeen years without subsequent harm. We should avoid touching a wound with the fingers as strictly as possible in all surgical operations, unless the sense of touch is for some reason indispensable. I have carried out this principle for two years, and have avoided danger of infection both to the patient and to myself.

DR. S. H. DURGIN: I think this matter of disinfection is a most important one, and Dr. Ernst's remarks call to my mind the fact that disinfection with the bichloride of mercury, and in fact with all of the disinfectants in solution is performed, as a rule, with great haste. The fact is oftentimes forgotten that it requires time in contact with a disinfectant in order for disinfection to occur. I think there is a very common impression that the mere touch of a disinfectant or a few moments' contact with infected material is sufficient to do its work, which is far from being true. Even the strongest disinfectants require time to do their work. An infection of the hand may be washed away with running water and soap and the hand be made fairly clean, but the use of an ordinary towel or of a disinfecting liquid in a basin for a few moments only, does not fulfil the conditions which experiments have shown to be necessary.

I want to correct an impression which Dr. Burr unintentionally gave when he alluded to the dressing of diseased meat at the abattoir.

The handling of all diseased animals and meat is provided for in the basement of the building and none but healthy animals are allowed to be slaughtered on the main floor. If disease in the animal escapes detection by the inspector and is found on dressing, on the main floor, the meat is at once removed to the rendering tanks in another building and the floors are immediately cleaned, so that no fear need be entertained as to any injury being done to the wholesome meats.

The regulations of the Board of Health cover the entire conduct of the abattoir and their enforcement is entrusted to Dr. Burr whose care and efficiency are undoubtedly. For the last two years diseased and unwholesome meats have been detected and condemned at the abattoir to an extent which was not possible under the former unskillful inspection.

DR. O. K. NEWELL: There is a law in this State which admits of the detention of a syphilitic case in the hospitals of public institutions. A syphilitic coming there may be detained for such time as is necessary to

make it safe to liberate him, although there are no special wards as yet for the treatment of this disease.

DR. WHITE: On the very last day of the last session of the Legislature, the committee to which this matter was entrusted, were enabled to push the matter through, so that the measures which our committee advocated, were essentially adopted.

Dr. Fifield has alluded to not finding the burrows in all cases. If he found them in one out of five or six cases, he would, I think, find them in as large a percentage as they occur. We do not expect to make a diagnosis of scabies by burrows alone, and it is only in the small proportion of cases I mention that they are found, that is, burrows so distinct that they can be recognized beyond question.

DR. H. L. BURRELL read a paper entitled

WHAT IS A FELON?²

DR. W. C. B. FIFIELD: A fair-sized volume might be filled with the anatomy, pathology, diagnosis and the treatment of what is called felon, sometimes known under the name of whitlow. The English surgical literature has contributed nothing, I may say, to the knowledge of this subject. Dr. Burrell would like to see the word felon abolished. I am afraid he can't. It is too firmly fixed.

To gain any knowledge of felon one must go to the French authorities who have occupied themselves with the subject for a good many years, and each one as he succeeds another has divided it into more and more classes, until the later surgical pathologists and anatomists have brought it down to three divisions. Dr. Burrell employs terms which are not familiar to me. The French surgeon, Bauchet, divides his cases into the superficial, subcutaneous and deep. By the superficial he would be understood to mean that which we know under the name of run-round. The commonest division that the French begin by is the subcutaneous, in French parlance, *bouton de chemise*, because the skin and the cellular tissue is elevated so that when the epidermis is raised by the purulent effusion, one finds a little hole beneath and leading down into the cellular tissue below the skin, through which pus escapes. The term abscess is very good, because we have the rounded place upon the top of the finger leading into an enlargement beyond. The real tendinous felon, such as Dr. Burrell has described, and to which he gives the name thecitis, is scarcely known to their pathology. Where pus exists in the sheath of the tendon, as it often does, it exists only in the two first phalanges of certain fingers. When pus exists at the terminal phalanges, the last phalanges, then it is necessarily periosteal, or inflammation of the bone, because the channel in which the tendon runs does not extend to the last phalanx. To that one must find exceptions, and the exceptions are these: in the little finger the tendon runs with the sheath to its very end; in the thumb the tendon runs with its sheath to the very end. This would follow, that, given a periosteal inflammation in the fore, middle and ring fingers, one is pretty sure that that does not follow the course of the tendon down into the palm of the hand. In fact, one never sees palmar inflammation follow disease of the terminal phalanges of the three first fingers, but let that disease attack the terminal phalanx of the little finger, and one occasionally sees the inflammation run, not only along the

tendon into the palm of the hand, but crossing over extend up the tendon of the thumb to its very end, and vice versa, an inflammation commencing at the terminal phalanx of the thumb may end with inflammation of the terminal phalanx of the little finger. That is a point to remember with regard to felon.

There is another form to which the term of felon is applied, to which the French give the term of the carbuncular inflammation. That, I think, nothing is known about here, hardly. I don't think surgeons recognize it when they see it. This occupies the back of the hand, along the hairy surface of the fingers, but it also occurs on the palmar side of the phalanges, where persons have been pricked with bones, a large poisoned wound which oftentimes takes on much the appearance of the periosteal inflammation, and one would be much tempted to give the wrong prognosis.

There is another kind of felon where the inflammation occurs, that is, beneath the pad at the root of the fingers. When the inflammation occurs there one expects in vain that pus is going to come out this way through this part of the hand. It comes through the web of the fingers, and although a person may see this opening within the web of the fingers, yet if he seeks the true source of the pus he finds it beneath these finger-pads, where corns are often formed, called *durillons forcés* in French.

In regard to the treatment of the periosteal form, I taught the students at the City Hospital the importance of making quick incisions, and tearing out at once the phalanx from its bed, not waiting for it to be cast off. Of course, this refers to the last phalanges. In regard to the inflammations of the palm of the hand, which sometimes follow the inflammations of the phalanges of the thumb and little finger, a very good thing used to be taught by French anatomists in my day, and that was in regard to what they call the M majuscule of the palm of the hand, and that is a good guide for operation, knowing as we do where the vessels run in the fingers: at the side one may safely carry the knife as deeply as he pleases, if he does not trespass beyond the first line of the capital M. Beyond that line he will get hemorrhage if he makes a deep incision.

There is a subject never taught here, I believe, by anatomists, and that is the palmar synovial pad, or sac, which resembles an hour-glass. By a careful dissection of the palm of the hand, getting off the palmar fascia and introducing the blow-pipe, you can inflate the whole of this pad so as to see that it extends beyond the annular ligament, and it is within this that pus forms in these destructive inflammations.

Specimen shown of finger removed from a patient with periostitis of the middle phalanx of the finger.

DR. J. C. WARREN: The etiology of these deep-seated inflammations about the bone and periosteum is an interesting one. The inflammation may be started in two ways. One is due to the bruising of the parts which disturbs the nutrition and renders it a soil favorable for the growth of the micro-organism which perhaps may be circulating in the system, that is, we may have an intravascular infection. My idea is that many of the inflammations known as felon occur without direct inoculation, but from within and through the agency of a trauma which interferes temporarily with the nutrition of the part.

Then again, the clinical history of this inflammation may possibly be known by the nature of the organism

² See page 108 of the Journal.

which plays a part; for instance, if we have the staphylococcus inflammation, we may have a localized abscess; if the inoculation of the streptococcus, we have the more rapid forms of spreading inflammation; therefore it may be due not merely to the anatomical nature of the part, but to the character of the virus which causes the spreading.

As to the locality, I should be inclined to regard the deep-seated inflammation, the true felon, as a periostitis in the majority of cases. It may possibly be in some of the cases an osteomyelitis, an inflammation starting from the interior of the bone itself.

In regard to the inflammations of the tendon, I should be inclined to regard them as more frequently secondary, as routes through which the suppuration may extend rather than as points of origin of the original inflammation.

In hearing what Dr. Burrell said about the treatment it occurred to me that a form of application which I use a good deal is, perhaps, as convenient and effective, and more comfortable than the hot poultice he recommended in the majority of cases, and that is carbolic acid in oil as a vehicle, in different strengths. It has a very soothing effect upon inflammation in this region, and it seems to exercise an antiseptic action. Many of the more superficial types of dermatitis or cellulitis, localized superficial inflammation, may be arrested by the application of a dressing with carbonized oil, 1 to 60 being sufficient for that purpose; and even after operations have been performed the dressing is a light one and pretty efficient. I have seen it stated that aqueous solutions of carbolic acid are dangerous to apply to the finger, the danger being that gangrene may follow. I never saw anything of the kind. I don't think pretty strong solutions of carbolic acid in oil are likely to do that.

DR. G. W. GAY: Dr. Burrell's very careful, clear and concise paper shows that he has had long and useful experience in the out-patient department. There is where one sees felons in all stages and varieties. It seems to me his division is a practical one, and after a person has worked awhile among them he will be able to recognize and classify them under one of these divisions. I have come to regard felons as capital cases of surgery rather than minor cases. In fact, I have come to tell the students that there is no minor surgery nowadays, so much is expected of surgeons. I think as much judgment can be shown in the treatment of felon as in almost anything, so as to get the patient well quickly and without deformity. I think in the majority of cases the patient should have ether. The pus should be found, if any there be.

It should be thoroughly evacuated and the wound treated with just as careful antisepsis as one would treat an amputation or laparotomy. I have seen many a case heal up with one dressing when treated in that way, and that is far better than the old way of poulticing and parboiling and the nasty, disagreeable fingers seen in old times.

In regard to the dressing with carbolic acid of which Dr. Warren speaks, I have seen a few cases. I think there was a lawsuit a few years ago in an adjoining town, where a finger was treated by being put in a watery solution of carbolic acid. This very day a patient came to my office with the skin of the two last phalanges of the forefinger entirely denuded by having been treated by a cloth wet in carbolic acid. The carbolic oil we have used at the hospital with a good

deal of satisfaction. I think, as a rule, a thorough, careful, antiseptic treatment, with incision, is the best way to manage the severe cases.

DR. F. B. HARRINGTON: I have been very much interested in this classification of Dr. Burrell's, and I think it is a good one. I have come, after seeing these cases daily in out-patient work, to feel that felons were merely septic wounds of the fingers. They are recorded as "septic wounds of the finger involving the bone," "the periosteum" or whatever part seemed to be most affected. I think, as Dr. Burrell has said, that these conditions very often run into each other. One can by seeking usually find the opening through which septic material has been introduced. If that is not possible, it is very easy to conceive of some minute opening being made through which septic material has passed.

The subject of destruction of tissues by the use of solutions of carbolic acid is one of great interest and importance. I have photographs of two cases in which fingers have been lost by the application of aqueous solutions of carbolic acid. This destruction of the tissues, carbolic necrosis, seems to take place most commonly where there is an incision or an abrasion of the skin.

It has seemed probable to me that the evaporation of the water had left the carbolic acid in considerable strength, and that its absorption into the tissues had caused the destruction.

DR. NEWELL: It would seem to me that if the title of Dr. Burrell's paper is to be answered in any way to apply to what is a felon, it must be that either a felon is some single thing or it is not. I had always supposed surgeons understood by felon that condition which occurs when we have tenderness arising without any external or superficial indications of disease. Tenderness over the anterior surface of the distal phalanx of one of the fingers, followed by acute pain on pressure and by the subsequent well-known symptoms, being a deep-seated suppuration. Any other affections of the finger which seem to be in consequence of skin manifestations of some sort are primarily of superficial origin and cutaneous diseases. I have always described as felon the above-mentioned deep-seated suppuration, which I think never can be anything but accidental, because although bruises are constantly occurring over the distal phalanges in manifold occupations, yet this deep tenderness, followed by extreme pain, tenderness and suppuration, is comparatively rare.

DR. RICHARDSON: Nothing interests the anatomist more than the surgery of the hand. I think the first two classifications—the peronychias and simple inflammations of the skin—should never be confused with the more serious forms; but it seems to me very difficult to distinguish periosteal from thecal inflammations. I have taught for many years that the proper way to treat such deep-seated inflammations, whether thecal or periosteal, was by careful dissections under complete anaesthesia until the pus is reached. I think this is the only safe method. By following a fixed rule always to cut deeply we invariably open the tendon sheath. This is not only unnecessary in many cases but absolutely unsafe and indefensible, for the reason that we often infect an otherwise healthy part by indiscriminate incisions. Yet if we must lay down a rule, I have no doubt that, on the whole, we should do better to follow that of long and deep cuts. Such a rule, amended as follows, would, I think, be safe to

adopt in all cases of deep inflammation in the palm or fingers, namely : A long incision should be made, under complete anesthesia, by careful dissection, until the source of the pus is found.

In regard to the point raised by Dr. Fifield as to the anatomy of the hand, I would say that these points were taught to me long ago by Dr. Porter. I have repeatedly shown the communication between the tental sheath of the flexor tendon of the little finger and the palm of the hand and also that between the thumb and wrist, through the sheath of the flexor longus pollicis. Dr. Mixer has made some very beautiful preparations to show this anatomical peculiarity. I have repeatedly observed the clinical confirmation of these anatomical tracts, not only by the extension of inflammation from the little finger into the palm of the hand and up to the wrist, but even extension into the terminal phalanx of the thumb. The reverse of this I have seen also ; where the sheath of the flexor longus pollicis becomes infected, the inflammation extends to the wrist, breaks into the bursa of the common flexors, and appears not only in the palm of the hand but even in the tip of the little finger. I think most surgeons to-day are familiar with and apply these anatomical facts to the surgery of palmar inflammation.

DR. H. W. CUSHING : The paper has been a very interesting one to me, since I have found this classification or a similar one very satisfactory for clinical work, especially for deciding what course of treatment is indicated in each special case. The main part of the paper I understand is in reference to this classification, and I wish to add my testimony as to its value. It is important, as Dr. Burrell and later Dr. Richardson have emphasized, in regard to treatment by incision. It is often a very unsatisfactory and unscientific method to indiscriminately treat these cases by a deep incision which extends to the osseous structure. I meet yearly in my hospital-work assistants who seem to consider such treatment the only proper method and see patients who have to their detriment, been so treated. If only one rule can be given, perhaps, all things considered, such a one would be the safest, since the most dangerous cases would be properly treated; but the indiscriminate deep incision is not a satisfactory method. An accurate diagnosis of the seat of the inflammatory process and a careful dissection give more satisfactory results.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

(Concluded from No. 4, page 97.)

FOURTH Annual Meeting, held in Richmond, Va., November 10, 11 and 12, 1891.

THIRD DAY.—MORNING SESSION.

DR. JAMES A. GOGGANS, of Alexander City, Ala., read a paper on

ABDOMINAL SECTION IN A CASE OF CYST OF THE MESENTERY.

He stated that he had been induced to write a paper on the case from the fact that cysts of the mesentery are extremely rare, and that operations for their removal are most generally fatal. He said that he had been able to find the record of one case of cyst of the mesentery removed by enucleation, by Guyon. The patient died on the seventh day after the operation.

One case operated upon by Sir Spencer Wells, the operator in that case incised and drained the cyst, but the patient died within a few weeks. Three cases operated upon by Pean, only one of which recovered. One case operated upon by Watts, but that he did not know the result in the case. One case operated upon by Cortes, who incised and drained the cyst, but the patient died from septicemia and hemorrhage. One case operated upon by Bantock, who removed the cyst by enucleation, and the patient recovered. The conclusion arrived at as to the origin of the cyst in that case, both by Dr. Bantock and the pathologist who examined the specimen, was that it originated from some foetal structure, possibly some of the rudiments of the permanent kidney. He said that Dr. Greig Smith says, that he knows of two cases of mesenteric cyst removed by operation by his friend, but that he could not relate them to him as they had not yet been published. He said that the patient upon whom he had operated for a cyst of the mesentery was a young woman, twenty-one years of age, daughter of a physician of Columbus, Ga. She had not been well for two years, but did not know that her abdomen was becoming larger until three months before the operation. During those three months she had been treated for abdominal dropsy, and had suffered much uneasiness and pain in the abdomen, and at the time of the operation her pulse was 120, and temperature 100° Fahr. The cyst was quite large, occupied mostly the left side of the abdomen, extended from under the ribs into the left lumbar region, dipped downward into the pelvis, and extended three or four inches beyond the median line of the abdomen into the right side. He said that he first removed about a quart of the fluid by aspiration, on February 7, 1891. The fluid was thin and of a dark color, and contained albumin, phosphates and chlorides. The patient was not benefited by the operation, and the abdominal section for the removal of the cyst was made on February 24, 1891.

The cyst was removed with omentum and mesentery, and loops of small intestine were embedded in its walls. An attempt was made to enucleate it, but hemorrhage was so free that the idea of enucleation was soon abandoned. A point as remote as possible from blood-vessels and intestines was selected, the cyst incised and drained. More than one gallon of a thin dark-colored fluid was evacuated, the sac irrigated with hot water, the lips of the incised sac stitched to the upper angle of the abdominal incision and a glass drainage-tube introduced to the bottom of the cyst. The abdominal incision was then closed with silk-worm gut sutures. The author was confident that the cyst was retro-peritoneal. The time consumed in the operation was twenty-five minutes. The sac was irrigated three or four times in twenty-four hours, and the drainage-tube gradually withdrawn. The patient suffered much from nausea and vomiting, which he attributed to the close connection between the walls of the sac and the loops of small intestines. The patient made a good recovery within thirty days. He presented a picture of the patient which was taken the 1st of November, 1891, which showed her to be in perfect health.

THINNESS OF UTERINE WALLS SIMULATING EXTRACERUTINE PREGNANCY, WITH REPORT OF TWO CASES,

was the title of a paper by DR. GEO. J. ENGELMANN, of St. Louis, Mo.

The author said there are many difficulties in the way of a positive diagnosis of early pregnancy, even in cases surrounded by conditions less unusual, but they assume alarming proportions when aggravated by the curious complications which may arise in individual cases, and above all when conditions are simulated in which delay is dangerous and operative interference seems called for, when a decision is urgently demanded, a decision upon which a life, and perhaps two, may depend. Whilst the auditor may criticize at his leisure and readily differentiate the conditions depicted, it is only he who is to pronounce and to act who can realize the difficulties of this entangling and so knotty problem.

CASE I. Patient, thirty-two years of age, had borne three children in the six and a half years of her married life, the youngest twenty months ago, which she was still nursing; and the menstrual flow has not as yet reappeared since the birth of this child. The patient came to his clinic for relief from a variety of discomforts from which she had been suffering more or less for the past three months. She complains of sick headache, vomiting spells, fulness of the stomach, belching after meals and an intermittent swelling of the abdomen; a pain in the groin appearing before such swelling, and a small tumor above the right groin, which she had first noticed three weeks ago, and, as she stated, then suddenly made its appearance. An examination revealed large varicose veins over the lower limbs; a solid, round, movable tumor above symphysis and right groin; the cervix low and large; the uterine body thickened lying low in the pelvis, with a certain mobility independent of the superimposed tumor; an applicator entering three and a half inches slightly ante. Notwithstanding the wine color of the pronounced cystocele and the cervix, pregnancy seemed out of the question, and the tumor was diagnosed as most probably a dermoid of the right ovary, hardly one connected with the uterine wall. In the course of an examination two weeks later, a very different condition of affairs was revealed. The tumor had disappeared, and a fetus was found in the utero-vesical space, freely movable, apparently floating about, the small parts being distinctly felt as if underneath a wet towel both through the vagina and abdominal walls. So distinct did the small parts appear to the examining finger, that it seemed impossible to realize that even as much as a thickness of the vaginal tissues should intervene, and the abdominal walls must certainly have been very much attenuated to disclose the fetal parts with such distinctness. Probe showed the uterine cavity free six and a half inches in length, still slightly ante, but never curving forward in the direction of the previous tumor.

The treatment for the supposed subinvolution was discontinued, the patient warned to keep quiet and to notify Dr. Engelmann upon the occurrence of any abnormal symptoms. He believed the case to be one of ectopic gestation, either within the broad ligament or in the abdominal cavity after tubal rupture, marked by the sudden appearance of the tumor five weeks ago, yet he was not sufficiently positive to warrant the immediate resort to the knife, and well that he did not do so, as persistent treatment and repeated examinations resulted in labor pains and the delivery of a five months fetus in the most correct and natural manner.

DR. ROBERT T. MORRIS, of New York, contributed a paper on

THE REMOVAL OF NECROTIC AND CARIOUS BONE WITH HYDROCHLORIC ACID AND PEPSIN.

The author said that it was sometimes desirable to remove dead bone without subjecting a weak patient to a dangerous or deforming operation. Attempts have been made, with some success, at clearing out this bone by a process of decalcification; but there are two chief reasons why failures have resulted, as a rule. In the first place, it was discovered that superficial layers of dead bone were decalcified easily enough, but the acids did not reach deeply through the mass, especially if portions were infiltrated with caseous or fatty débris. In the second place, cellulitis was pretty apt to develop during the course of treatment.

After much experimentation he had finally adopted a method of work which seemed to be complete. An opening is made through soft parts by the most direct route to the seat of dead bone, and if sinuses are present they are all led into the one large sinus, if possible. The large direct sinus is kept open with antiseptic gauze, and the wound allowed to remain quiet until granulations have formed. Granulation tissue contains no lymphatics, and absorption of septic material through it is so slow that we have very good protection against cellulitis. The next step consists in injecting into the sinus a two or three per cent. solution of hydrochloric acid in distilled water. If the patient is confined to bed, the injections can be made at intervals of two hours during the day; but if it is best to keep the patient up and about, the acid solution is thrown into the sinus only at bedtime. In either case the patient is to assume a position favorable for the retention of the fluid. Decalcification of exposed layers of dead bone takes place quickly, and then comes the necessity for another and very important step in the process. At intervals of about two days an acidulated pepsin solution is thrown into the sinus¹ and this will digest out decalcified bone and caseous and fatty débris in about two hours, leaving clean dead bone exposed for a repetition of the procedure. The treatment is continued until the sinus closes from the bottom, showing that the dead bone is all out.

Even in distinctly tuberculous cases the sinuses will close²; apparatus for immobilizing diseased parts and tonic constitutional treatment are employed, as they should be, in conjunction with our efforts at removing the dead bone. If suppuration is free in any cavity in which we are at work, it is well to make a continual practice of washing out the cavity with peroxide of hydrogen before each injection.

It is a popular impression in the profession that living bone is not attacked by dilute mineral acids, but as it makes a good deal of difference whether the impression is correct or not, he experimented as follows: A portion of the keratinoid layer was removed from the carapace of a turtle (*nanemys guttata*), and the animal was then placed tail downward in a glass of five per cent. hydrochloric acid solution. In the glass he placed also a segment snipped from the plastron of the turtle, and a transverse segment from an old dry humerus of a man. The piece of humerus was completely decalcified in six hours; the segment from the plastron was soft in about twenty hours, and the carapace of living bone was decalcified at the exposed part in thirty hours. He was then curious to know what effect the acid had had upon the blood-vessels of the

¹ He uses distilled water, 3*iv*; hydrochloric acid, m. xvi; Fairchild's pepsin 3*ss*.

decalcified bone; and Dr. Smith of the laboratory of the Post-Graduate Medical School made for him several sections of the carapace, which included both decalcified and healthy bone. Investigation showed that all of the blood vessels were destroyed wherever the bone was softened, and the action of the acid had extended farther up along the larger blood-vessels than elsewhere.

The difference in time between decalcifications of the dead bone (six hours) and of living bone (thirty hours) is significant; a five per cent solution of the hydrochloric acid having been used. If we use a two or three per cent. solution of hydrochloric acid, a wall of lymph and of granulation tissue is thrown out upon the surface of the living bone for protection, and only dead bone is attacked. This at least has been his observation in several cases in which the results of treatment could be easily watched.

DR. LANDON CARTER GRAY, of New York, in a paper entitled

THE PRESENT STATUS OF CEREBRAL SURGERY, touched upon the modern aspect of intracranial surgery. The speaker first passed in review our present knowledge of localization of functions of the brain, stating that we were well acquainted with the functions of the motor area, of the third frontal convolution, the frontal lobe, the island of Reil, the two upper temporal convolutions, the cuneus, certain portions of the basal ganglia, the base of the brain and the cerebellum, and that we knew nothing of, or had still under discussion, the question of the localization of the centres for the sensations of touch, pain, muscular sense, temperature sense, most of the parietal lobe, and most of the temporo-sphenoidal lobe with the exception of the olfactory lobe. He stated that operations for fracture of the skull with or without haemorrhage, for abscesses, and for tumors that were removable and localizable were usually successful; those for so-called idiopathic epilepsy were utterly valueless, as were also those for epilepsy supposed to be due to genital or ovarian irritations, whilst those done for epilepsy due to removable and localizable lesions of the intracranial contents were usually successful so far as the lesion was concerned, although it was a grave question as to whether the epileptic habit was ever cured. The latest operation for idiocy supposed to be due to premature ossification of the fontanelles was still under discussion and consideration, the cases being too few and too recent to permit of any conclusion; whilst the operations for hydrocephalus and for epilepsy due to such early infantile and foetal lesions as parencephalus, haemorrhage and meningitis were indefensible. He further impressed upon surgeons the great difficulty that there often was in finding a subcortical lesion of the centrum ovale that was deep-seated or small; and the fact should be borne in mind that there might be no decussation of the motor fibres from the hemispheres, so that a lesion would be found upon the same side as the paralysis.

THIRD DAY — AFTERNOON SESSION.

DR. CHRISTOPHER TOMPKINS, of Richmond, Va., followed with a paper entitled

A CASE OF INDUCED ABORTION FOR RELIEF OF NAUSEA AND VOMITING, WITH REMARKS.

On August 1, 1885, he was called to see Mrs. J., aged twenty-four, and, as nearly as could be ascertained,

three and a half months pregnant with her first child. Patient was born in the mountainous part of Virginia; she had an active out-door life and grew up to be a woman of good height and of round full figure. January 14, 1884, she was married. While in the City of New Orleans, in stepping from the platform of a car, she sprained her ankle. This, although treated immediately by a physician of that place and subsequently in this city, caused her great suffering. Finally, refusing to yield to the usual treatment, the part was put in a plaster cast; she went about on crutches, and after many months recovered. In the mean time she became pregnant, and from the first was attacked with nausea and vomiting. Mild in the beginning, it gradually increased in gravity, till she sent for him on the 1st of August, 1885.

Her husband stated that she had had a fever for two weeks. Dr. Tompkins found her in bed, and learned that she had been there for days; her figure not robust, and her face thin and attenuated. What little she had eaten in the past ten days or two weeks had been apparently rejected, her temperature one degree above normal; tongue foul; sores on the teeth, and the breath of a sour and bilious odor. The pulse was fairly good, considering her condition. Even the mention of food was distressing to her, and the sound of the dinner bell, though far off from her, caused such distress, that its ringing was discontinued by the family. The bowels had throughout her pregnancy been constipated, only moving once in two or three days. Although continuously retching, very little or no blood had been seen in the material vomited, except on two occasions, and then not a great deal, and such as there was, was of a florid scarlet color. No medicine had been given and no treatment taken, except the occasional use of lime water, which she said "did no good."

The patient did not improve up to August 7th, when Dr. Tompkins, thinking the case one of the greatest gravity, and that the question of abortion could no longer be deferred, invited Drs. J. B. McCaw and Aaron Jeffery to meet him in the afternoon in consultation. All agreed that abortion must be produced, in order to give the patient a last chance for her life, which was done.

Remarks. — The case is reported principally because it was an unsuccessful one, and because he wished to disabuse the minds of those who are not experienced in such operations of the notion, commonly believed and often expressed, that the induction of abortion for the nausea and vomiting of pregnancy is in skilful hands an undertaking devoid of danger and necessarily attended by success. In this case, he is of the opinion that death was the result of the protracted debility and emaciated constitution, due to her long confinement and suffering, caused first by the injury to her ankle, from which she had not recovered when she became pregnant and was attacked by nausea and vomiting, this last continuing till her death. Under such circumstances the outlook was indeed very unfavorable, for to the shock of operation and depression incident to the use of chloroform, there was added fever and protracted prostration, both from injury to the ankle and from want of nutrition, the result of the long-existing nausea and vomiting. He had before and since operated on women for the nausea and vomiting of pregnancy and with success, whose apparent condition was much worse than that described in the above case, but without the history of a previous injury or disease.

The prognosis, always unfavorable, ought, when the case is so complicated, to be of the most guarded kind. The practitioner should not, however, hold his hands on this account, for the operation affords the poor sufferer the only opportunity of relief. The author uses metal dilators instead of tents, and completes the operation at one sitting. He is likewise convinced that the least possible chloroform used, the better the result.

The following officers were elected: President, Dr. McFadden Gaston, Atlanta, Ga.; First Vice-President, Dr. Cornelius Kollock, Cheraw, S. C.; Second Vice-President, Dr. Geo. Ben Johnson, Richmond, Va.; Secretary, Dr. W. E. H. Davis, Birmingham, Ala.

Place of next meeting, Louisville, Ky., second Tuesday in November, 1892. Chairman of Committee of Arrangements, Dr. L. S. McMurry, Louisville, Ky.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

STATED meeting held January 25, 1892.

DISCUSSION ON EPIDEMIC INFLUENZA.

DR. EDWARD G. JANEWAY opened with some remarks on the diagnostic features of the affection. An isolated case of it, he said, could not be put into the category of having fixed characteristics, but a number of cases taken together justified the diagnosis of epidemic influenza. Having spoken of the numerous phases assumed by the disease in different instances, he said that there was a tendency, in the presence of the epidemic, to class ordinary diseases under the head of influenza. Follicular tonsillitis, pneumonia and meningitis were some of the afflictions sometimes mistaken for it, and the early symptoms of small-pox might also be taken for those of influenza.

DR. R. W. WILCOX thought that epidemic influenza has certain marked characteristics which clearly distinguish it from other diseases. Among these he mentioned: (1) the suddenness of the attack; (2) the multiplicity of the symptoms; (3) the variability of the symptoms; (4) an amount of depression not at all proportionate to the physical trouble; and, (5) the progress of convalescence, which is more tardy than in other diseases of the same severity.

DR. WM. H. DRAPER spoke on the complications and sequelae of influenza, and stated that in his opinion most of the so-called complications were in reality manifestations of the disease.

DR. T. R. POOLEY, in speaking of the eye complications, said that it would take much less time to talk about the diseases of the eye which were not thought to occur in the grip, or as sequelae to it, than of those which had been mentioned in this category, and he expressed the opinion that influenza was held to blame for many diseases of the eye with which it had nothing whatever to do.

DR. O. D. POMEROY spoke of the ear complications, and DR. BEVERLEY ROBINSON described a curious aural condition he had met with, in which the patient could not hear words spoken in an ordinary tone, but could distinguish the ticking of a watch placed at some distance from the ear.

DR. H. D. CHAPIN, who spoke on influenza in children, coincided in the opinion generally held that they are less subject to the disease than adults. He called attention also to the necessity of caution in

diagnosing as influenza diseases entirely distinct from it, and referred to an instance in which a whole family of children had been exposed for several days to measles, because a case of that disease was declared to be influenza.

DR. LANDON CARTER GRAY spoke of the nervous phenomena of the disease, and DR. FRANCIS DELAFIELD, of the treatment. Dr. Delafield thought there was no treatment to prevent it, and none to affect its course, any more than there was in other infectious diseases. The chief things were that the patient should be kept in bed and properly nursed. There were, however, the frequent complications which called for interference. For the headache and neuralgic pains phenacetin was most relied upon. The bronchial affections should be treated in the ordinary way, and when there was a tendency to congestion of the lungs, it was advisable to work on the circulation, giving small and frequent doses of digitalis or aconite, with or without strichnina, and perhaps alcoholic stimulants.

Recent Literature.

Age of the Domestic Animals: Being a Complete Treatise on the Dentition of the Horse, Ox, Sheep, Hog and Dog, and on the Various other Means of Determining the Age of These Animals. By RUSH SHIPPEN HUIDEKOPER, M.D. Two hundred engravings. Philadelphia and London. 1891.

Dr. Huidekoper's reputation is *prima facie* evidence of the value of this book. As would naturally be expected, the greater part of it is devoted to the dentition of the horse. The various conditions of the teeth are illustrated by a very large series of figures, rather grandiloquently called on the title-page "engravings." Much space is given to the important subject of dental irregularities. Under this head are included, not only anomalies of development and structure, but the effects of too much or too little use, of "cribbing" and also fraudulent changes. The determination of the age by the horns is discussed in the cases of cattle, sheep and goats. There is also a short chapter on the age and teeth of man, which contains nothing new excepting the statement that "from a practical point of view the question of the age of man is one of sentiment." In a scientific work it strikes us as very far from a sentimental question.

The chapter on the duration of the life of the horse begins as follows: "According to Buffon, the duration of the life of the horse is, as in all other species of animals, proportionate to the duration of its growth. Man, who is fourteen years in growth, lives six or seven times that length of time; that is to say, he may live to ninety or one hundred. The horse, which requires about four years to attain its growth, may live six or seven times that length of time, that is, to twenty-five or thirty years." The part of this which applies to man is too silly for criticism. The introduction of such passages tends to shake the reader's confidence in statements on matters with which he is unfamiliar.

A LAW has been passed at St. Petersburg that a doctor who takes charge of an accident which he may happen to attend on the street shall be paid by the police in proportion to the importance of the case.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, FEBRUARY 4, 1892.

TYPHOID FEVER IN CHICAGO.

Among the manifold advantages of Chicago from a sanitary standpoint, the superiority and perfection of its water-supply may well be reckoned as one of the greatest. Situated on the site of one of the most magnificent bodies of fresh water on the face of the earth, its opportunity of securing an unlimited supply of this necessity of life is unequalled. The best water in the world and the best adapted for culinary and domestic purposes is to be had for the cost of pumping, and the consequence is that the community has been duly improved, the city to-day enjoys the supreme advantage of a constant supply of this most essential element.—First paragraph of a well-concentrated article in the Chicago *Sunday Tribune*, December 13, 1891.

This article goes on to compare the water-supply of Chicago with those of other great cities of the world to the advantage of the former.

Health Commissioner Ware said yesterday (January 29th): I am certain that typhoid fever is not epidemic in Chicago, though I will say that it is more prevalent than I would like. The fact is not unconnected with the dredging and deepening of the river, due to the lack of sufficient pumping capacity at Bridgeport. It would be useless to deny that the river flows at present in a condition right out of the lake. I need not say how dangerous such a state of things is to the health of the city. The shore, too, is being gradually growing towards the main crib. How long the four-mile tunnel could be in operation next summer, and that all our water-supply could be obtained from a part of the lake beyond pollution.—Chicago *Tribune*.

There is something pathetic in Health Commissioner Ware's statement, and let us for the completion of the water-tunnels into the lake and for the completion of the four-mile tunnel. Everything urged by Dr. Ware for the improvement of the water-supply in quality and for the increase in quantity ought to have been done months and months ago. . . .

There is no immediate prospect for that rate at which the Health Commissioner so pathetically urges. Cannot the city authorities take note of the emergencies? Cannot Mr. Underwood hurry up the work on the four-mile tunnel so that it may be available next summer? Will not the Council, instead of wasting money in extending the north shore tunnel, use the money in extending the tunnel along the lake beyond the two-mile crib to a region of absolutely pure and wholesome water in the lake which the shore pollution cannot reach?

The four-mile tunnel, the completion of which is looked forward to with so much anxiety, since it is plain that the people must rely on it for pure water, as the Drainage Board will do nothing for them. . . .—Editorial columns, Chicago *Tribune*, January 31, 1892.

A paper entitled "Statistics on Typhoid Fever in Chicago," by Prof. Wm. T. Sedgwick, of the Massachusetts Institute of Technology, and Mr. Allen Hazen, chemist to the Massachusetts State Board of Health at Lawrence, was read before the American

Statistical Association on January 22d, and on the same day an abstract of the paper was published in the Chicago *Tribune*.

At the end of this original article on January 22d, Health Commissioner Ware of Chicago, pronounced the statement "ridiculous," and when asked if there had really been 2,000 deaths from typhoid fever in 1891, as therein stated, said: "You may most emphatically deny the assertion; this is done probably to hurt Chicago, the assertions made are so ridiculous that they answer themselves. There is no sort of an epidemic of typhoid fever, and has not been. This scare is started to frighten people from coming to the World's Fair." But the *Tribune*, January 23d, showed from the returns at the Health Department that the figures given by Messrs. Sedgwick and Hazen were correct, and that there had been 219 deaths from typhoid fever already in January, 1892. Their conclusions are inevitable. The State of Illinois has appointed Dr. John H. Rauch, formerly Secretary of the State Board, to investigate and report on the subject.

We have headed these remarks by parallel columns merely to show the need of such an exhibit of the actual facts as that made in the paper of Messrs. Sedgwick and Hazen, but have nothing except praise for the instant and candid recognition of this by the Chicago *Tribune*.

Messrs. Sedgwick and Hazen illustrated their paper by several tables of figures and two diagrams showing most graphically the mortality percentages of typhoid fever in Chicago, Philadelphia, New York and Boston between 1870 and 1891, and the rate of subsidence of the disease in Chicago after 1872, 1881, and 1885, in each of which years the number of cases was very large. We regret that we cannot reproduce these, but append an abstract of the paper furnished us by the writers.

It does not appear to have been generally recognized that within the last two years, and especially within the last nine months, typhoid fever has been unusually prevalent in the city of Chicago. The fact, however, is that an epidemic of really alarming proportions has prevailed in Chicago within the last year, and the latest returns indicate that that city is still suffering very severely from this important disease. Inasmuch as a World's Fair is soon to be opened in Chicago, this unfortunate condition becomes of more than local consequence, and should excite grave apprehension. If any remedy exists it ought to be found and applied without delay. It is especially important that the sanitary condition of Chicago in 1893 should be above reproach, because that of Philadelphia in 1876 was not. At the time of the Centennial Exhibition there was much complaint of the sanitary condition of Philadelphia. Physicians can testify that numerous cases of typhoid fever, which came under their observation in 1876, appeared to be plainly traceable to infection received in Philadelphia.

There was apparently ground for suspicion and complaint, for the official report of the Board of Health of Philadelphia, for 1876, relates that before the opening

of the exhibition "no little anxiety and solicitude for the welfare of the city was manifested, since many of the conditions favorable to the propagation of disease were present." This report also states that "no feature in the mortality records of 1876 is more interesting than the increase in the number of deaths from typhoid fever. There were 773 deaths from this disease, a number which is nearly double the mortality of the previous year, and which has not been approached in value since the year 1865."

By comparing the population of Philadelphia, in 1876, with the number of deaths from typhoid fever, we find that the death-rate from this disease for the Centennial year was remarkably high, namely, 9.36 per 10,000 inhabitants. The percentage of all deaths due to typhoid fever was also very high, namely, 4.09. Since 1876 there has been a great increase in the population of Philadelphia, and therefore in the annual number of deaths; but the number of deaths from typhoid fever per annum has never been as great as in that year, excepting once, and that only after twelve years, in 1888.

In the city of Chicago there has been for many years a large amount of typhoid fever. It was abundant, for example, in 1872, in 1881, in 1885 and in 1886. Between 1886 and 1890, however, it was less common, but in 1890 the death-rate from typhoid fever suddenly rose to a height almost exactly the same as that reached by Philadelphia in 1876, namely, to 9.16 deaths per 10,000 inhabitants, and 4.16 per cent. of all deaths which occurred in that year. In other words, typhoid fever prevailed as extensively in Chicago in 1890, as in Philadelphia in 1876. The actual number of deaths in Chicago, in 1890, from typhoid fever was, 1,008.

Remarkable as these figures were, they proved to be only the prelude to others still more remarkable in 1891. During the year just ended, Chicago has reported 1,997 deaths from typhoid fever, giving the prodigious death-rate from this disease of 16.64 per 10,000 of population, and a percentage of all deaths of 7.19. In the month of May alone, there were 408 deaths from typhoid fever reported. This is more than one-fourth as great as the whole number of deaths from this disease reported by the State Board of Health for the entire year before in the whole State of New York, containing six millions of inhabitants, and including two of our largest cities, New York and Brooklyn. In the single month of May, 1891, there were more deaths from this disease in the city of Chicago than in the city of New York during the whole twelve months of 1888 or 1889 or 1890 or 1891. In 1891 there were 383 more deaths from typhoid fever in Chicago than were reported in the previous year in the whole State of New York with five times the population, and nearly 1,400 more deaths than in London, with three and one-half times the population of Chicago.

As has just been stated, the whole number of deaths from typhoid fever in Chicago, in 1891, was 1,997. If

we multiply this number by ten we shall have an approximate estimate of the whole number of persons affected by this disease during the year, namely, about 20,000. This indicates that more than one and one-half per cent. of the whole population was affected in 1891 by a disease which is now classed as preventable.

It does not seem probable that these extraordinary figures can be surpassed, or even maintained in 1892 or 1893, but as an indication of the sanitary condition of Chicago, they must be a source of constant anxiety to its citizens, as they certainly are a menace to the sanitary success of the World's Fair.

We may now turn to an examination of the history of typhoid fever in Chicago. The necessary data are given in the official reports of the Department of Health of the city of Chicago. We cannot agree with the author of the statement in the annual report of 1872, that "although the overcrowding and barrack-life incident to the months following the great fire in October, 1871, brought its legitimate result in an increased death-rate, during the year no epidemic existed." The fact is, that in that year the death-rate from this disease and its percentage of mortality to the total mortality were greater than they have ever been since that time, until the present epidemic had developed. After 1872, there was a marked improvement until 1879, when there was a slight increase, followed by a great increase in 1881. The fever then slowly subsided until 1885, in which year there was another marked increase, followed by a decline in 1886, 1887, and in 1888. In 1889, a rise began which obtained the proportions of an epidemic in 1890, and reached the great height already referred to in 1891. The epidemic of 1872 fell off very rapidly in 1873; that of 1881 declined much more slowly; that of 1885 also slowly, so that unless some special effort is made to hasten the decline of the present epidemic, there is fear that typhoid fever may continue to be very prevalent in Chicago in 1892 and 1893.

In the next place we may inquire whether typhoid fever has been, on the whole, increasing or decreasing in Chicago. From 1871 to 1880 the average death-rate per 10,000 inhabitants, from typhoid fever, was 5.86. From 1881 to 1890, 6.75. The conclusion is inevitable that typhoid fever has, on the whole, increased in Chicago since 1880, while, within the last two years, it has risen to an extraordinary height.

We may next inquire how Chicago regularly compares with other cities in respect to mortality from typhoid fever. Here we naturally turn first to the larger American cities. We may begin with New York and Philadelphia. The averages of these cities are as follows: Chicago, 1870-1891, death-rate per 10,000, 6.90; New York for same period, 3.19; Philadelphia, 6.24. The death-rate from typhoid fever of all the cities of Massachusetts, 28 in number, for the twelve years 1878-1889 was 4.62 per 10,000 inhabitants, that of Boston being 4.32. The rate for Chicago during these years was 5.85. Turning to foreign cities, we may compare the following with Chicago:

Dresden, 1889,	mortality per 10,000 inhabitants	0.8
Leipzig, 1889,	"	"	"	.	.	.	1.7
Munich, 1889,	"	"	"	.	.	.	1.1
Cologne, 1889,	"	"	"	.	.	.	1.6
Berlin, 1889,	"	"	"	.	.	.	2.0
London, 1889,	"	"	"	.	.	.	1.4
Chicago, 1889,	"	"	"	.	.	.	4.7
Chicago, 1891,	"	"	"	.	.	.	16.6

From the foregoing facts it appears: (1) that typhoid fever has been excessive in Chicago for many years; and (2) we have already shown that it is, on the whole, increasing; while (3) within the last two years it has risen to extraordinary proportions.

In order to avoid misapprehension it ought to be stated, however, that the total death-rate of Chicago, as that term is best known and most often used, is not excessive. It has had since 1881 fewer total deaths in proportion to its population, than New York, and a much lower general death-rate. In respect to typhoid fever, however, the case is exactly reversed.

Although the paper is essentially statistical, the authors suggest that considering the prevailing views regarding the causation of typhoid fever, the question should be raised whether the water-supply is above suspicion. They prove briefly that this is by no means the case, for the paper closes with a number of quotations from the official reports of the health department of Chicago and the Illinois State Board of Health, describing the unsanitary condition of the Chicago River, and proving that the water-supply of Chicago is occasionally polluted with sewage. The authors urge, in view of all the facts, that immediate action be taken to check the epidemic and especially to protect the purity of the water-supply.

It is gratifying to learn that active measures are being taken to protect the water-supply by the opening of a new crib out some four miles, and by deepening the drainage canal towards the Mississippi.

The attitude of the *Tribune* is an indication that the public of Chicago will insist on having the necessary improvements carried out, and that they will not rest contented with the mere assertion that they have at their doors the best and biggest supply of drinking-water of any city in the world. In view of the World's Fair, and for those who realize how widely a few cases of typhoid fever may distribute the disease over a whole country, this is no longer a local question. The health commissioner of Chicago is ill advised in announcing that such a statement of figures from his own office is published "to injure Chicago"; or in attempting to break its force, as he now does, by calling in question the accuracy of the returns made by Chicago doctors, or attributing the cases of typhoid which he knows have occurred, to the bad air of the alley-ways! There probably are inaccurate returns of disease in Chicago as in other large cities, and there probably is some neglect to return at all; but we doubt if the Chicago practitioners are so pre-eminently inaccurate above those of other cities, or take especial satisfaction in returning this particular disease.

Given an unusual percentage of typhoid fever all the time, or at frequently recurring intervals in a par-

ticular city, and it is almost certain that something is wrong either with the water-supply or the drainage, or both. Bad drains and bad water are never so dangerous as when they are persistently proclaimed to be good.

MEDICAL NOTES.

VACCINATION IN ITALY.—On the first of the year, a new vaccination law went into force in Italy which makes vaccination compulsory. There is also a provision for re-vaccination under certain conditions.

THE SOUTH AMERICAN MEDICAL CONGRESS will meet this year in Cuba, in October, in order that it may be held at the same time with the celebration in honor of the four-hundredth anniversary of the discovery of America, to be held in that city.

THE THERAPEUTIC GAZETTE.—Dr. R. A. Smith has retired from the editorship of the *Therapeutic Gazette*, which will hereafter be under the charge of Dr. H. A. Hare. Dr. G. E. de Schweinitz will be editor of ophthalmic and aural therapeutics, and Dr. Edward Martin editor of surgical therapeutics.

THE INFLUENZA IN LONDON.—During the week ending January 16th, the number of deaths due directly to the influenza rose to 271 from 95 the previous week. This does not include the large number of cases in which influenza was reported as a complication. During the week ending January 23d the number of deaths primarily due to influenza rose to 506, and the total mortality to more than double the usual rate. There seems to be an excitement almost amounting to a panic among certain classes in the community. Since the death of the Duke of Clarence, the government has decided to institute an official investigation of the disease, with the view of taking any possible measures for its limitation. The Archbishop of Canterbury has issued a special prayer against influenza.

LADY BROOKE'S REMEDY FOR INFLUENZA.—It is reported by cable from England that Lady Brooke has been trying to raise a fund for the gratuitous distribution of about 2,000 bottles of brandy among the poor who were suffering from influenza, on the theory that stimulants are the best treatment for the disease. As might be expected, the project did not meet with a very favorable reception.

THE NEW YORK CITY INSANE ASYLUMS.—The committee appointed by the Mayor of New York to visit the insane pavilions on Ward and Blackwell's Islands, have found that in all the eleven buildings provided for patients in different stages of insanity, there are accommodations for 1,091 at the utmost, yet there are now in the institution 1,817 patients crowded close together. Every single room in the main asylum has from four to six beds in it, when there should be only one. Even in the corridors, which were originally provided with alcoves to be used as sitting-rooms, beds are ranged along the walls so close together that the patients have to climb in over

the foot-boards in order to get in at all. In what is known as the violent pavilion, about 280 unfortunates are crowded into rooms originally intended for 190 persons.

LABORATORY OF HYGIENE, UNIVERSITY OF PENNSYLVANIA. — It is announced that the laboratory of hygiene of the University of Pennsylvania will be opened for practical work on February 1, 1892. The work of the laboratory will be under the charge of the director, Dr. John S. Billings. Dr. A. C. Abbott has been appointed first assistant, and Dr. Albert A. Ghriskey, assistant in bacteriology. A course in practical hygiene and an elementary course in bacteriology, each of eight weeks, have been established.

NEW ENGLAND.

ASSISTANT PORT PHYSICIAN. — Francis A. Lane, M.D., has been appointed assistant port physician by the Mayor in place of Rufus E. Darrah, M.D., resigned.

LAST WEEK'S DEATH-RATE IN BOSTON. — The number of deaths in Boston last week was 225, against 181 the corresponding week last year. The death-rate was 25.4. The number of deaths from consumption was 35, pneumonia 39, bronchitis 16. The number of persons over sixty years of age was 59. Seventeen deaths were reported as due to influenza, of which twelve were complicated with some other disease. Since the week ending January 9th the fatal results of the epidemic have been steadily diminishing.

BREQUESTS TO INSTITUTIONS IN SALEM. — By the will of the late George Peabody, of Salem, \$5,000 is left to the Salem Hospital, \$2,000 to the Peabody Institute, \$1,000 to the city of Salem, the income to be used to purchase fuel for the very poor.

THE USE OF TOBACCO BY MINORS. — The Committee on Public Health of the Massachusetts Legislature will give a hearing to parties interested in a petition for legislation to prevent the use of tobacco by persons under sixteen years of age, on Friday, February 5th, at 11 o'clock.

HOSPITAL FOR EPILEPTICS. — The Governor of Massachusetts has sent a message to the House recommending a State institution for adult epileptics, with the report of the committee of the Massachusetts Medical Society appointed to consider the matter. The State Board of Lunacy and Charity has indorsed the recommendation. In conclusion, the governor says: "In my judgment, the facts and reasons stated in the communication entitle the recommendation to your early and favorable action. I specially commend the suggestion that the institution, if established, should be in the form of cottage hospitals."

MASSACHUSETTS ASSOCIATION OF BOARDS OF HEALTH. — The annual meeting of the Association was held in Boston last week. Several papers were read and the following officers were elected for the

year: President, H. P. Walcott, M.D.; Vice-presidents, S. H. Durgin, M.D., S. W. Abbott, M.D.; Secretary, L. F. Woodward, M.D.; Treasurer, J. B. Field, M.D.

DRINKING-WATER OF MASSACHUSETTS. — The report of the State Board of Health recently transmitted to the Legislature shows that the low water in the streams of the State during the summer and autumn has been accompanied by a much greater degree of pollution in those streams which receive sewage, than has been noted at any time since 1887. During the summer a large number of the spring waters sold for drinking purposes, were collected for examination and careful inspection of the surroundings of the springs were made. Some of these springs, situated in populous districts, were found to have a large amount of pollution. Much time has been spent during the year in the study of typhoid fever in relation to the water-supply. The Board recommends the continuance of the investigations already commenced, and also others indicated as desirable. For these purposes, it is estimated that \$27,000 will be required.

MORTALITY OF NEWPORT, R. I. — During the past year there were 431 deaths reported, a large increase in the number for some years passed. The annual death-rate was twenty-one per thousand as against seventeen in 1890, and less than sixteen for three previous years. There was a marked increase in the number of deaths due to pneumonia and senile asthenia, undoubtedly due to influenza. The average age of the decedents was forty years, the average age of those dying from consumption was thirty-seven years.

NEW YORK.

A DIAGNOSIS OF ALCOHOLISM. — A coroner's jury has censured the ambulance surgeons of the Chamber Street Branch of the New York Hospital, for refusing (on the ground that it was a case of drunkenness) to take to the hospital a man who was suffering from a fracture of the skull resulting from a fall into the hold of a steamship. The verdict in the case concludes as follows: "We recommend that in cases where there is any doubt whether an injured person is suffering from alcoholism or not, the same should, under all circumstances, be taken to an hospital for a closer examination."

STATE CARE OF INSANE. — Mayor Grant has appointed an advisory committee of prominent citizens, one of them the President of the Tax Department, to report upon the advisability of the city's availing itself of the provisions of the law passed in 1890, relative to State care of the insane, which permits the city to turn over its insane to the State, if it should not desire to continue to care for them itself. Under the statute, if the city elects to entrust its insane to the care of the State, it must also transfer to the State all the buildings it now has in use for this class of dependents. In his recent annual message, the Mayor showed that the cost to the city of maintaining its insane is about

\$500,000 a year, and that the overcrowded condition of its asylum buildings renders necessary the early erection of more, unless the whole matter is turned over to the State.

HEALTH OFFICER OF THE PORT.—The Governor has appointed Dr. William T. Jenkins, of New York, to the important position of Health Officer of the Port, which has been held since 1880 by Dr. William H. Smith. While this is a political appointment, it is generally regarded as an excellent one as far as the qualifications of the new officer are concerned. Dr. Jenkins was born at Holly Springs, Mississippi, in 1855. He studied medicine at Bellevue Hospital Medical College, New York, and at the University of Virginia, from the latter of which he graduated. He settled in New York. In 1882 he received the appointment of Coroner's Physician, and afterwards became Deputy Coroner, in which position he is now serving his fourth term. By his appointment Dr. Jenkins becomes *ex officio* a Commissioner of the New York Board of Health, the other members of which are Charles G. Wilson, President, Dr. Joseph D. Bryant, and President Voorhis of the Police Board.

A CASE OF SNAKE-BITE.—While handling her reptiles the other day in a dime museum on Fourteenth Street, a female snake-charmer was bitten in the cheek by a large rattlesnake. One of the other performers promptly put his lips to the wound and sucked out as much of the poison as possible, and after being well dosed with whiskey the woman was taken to the New York Hospital, where she is in a fair way to recovery. It is stated that this is the third time that she has been bitten by a rattlesnake.

ANNUAL ELECTION OF OFFICERS.—At the annual meeting of the New York County Medical Association held January 18th, the following officers were elected: President, Dr. S. B. Wylie McLeod; Vice-president, Dr. Wm. T. White; Recording Secretary, Dr. P. Brynberg Porter; Corresponding and Statistical Secretary, Dr. Augustus D. Ruggles; Treasurer, Dr. John H. Hinton; Member of the Executive Committee, Dr. Beverhont Thompson. The Statistical Secretary reported that during the year the membership had been increased by 148, and that there were now 701 names on the roll. At a meeting of the Section on General Medicine of the Academy of Medicine, held January 19th, Dr. A. A. Smith was elected Chairman and Dr. Charles E. Quimby, Secretary. The Board of Directors of the New York Post-Graduate Medical School and Hospital has re-elected the following officers for the ensuing year: President, Dr. D. B. St. John Roosa; Vice-president, Dr. George H. Fox; Secretary, Dr. Clarence E. Rice; Treasurer, Dr. L. Bolton Bangs. Four hundred and eighty-three practitioners of medicine, from the United States, Canada and the West Indies, attended the courses at the school during the past year, and as the present quarters are inadequate for the growing wants of the institution, the Directors propose erecting a new college building as soon as the necessary funds can be secured.

Miscellany.

BICARBONATE OF POTASH IN INFLUENZA.

SOME months ago Mr. John Crerar¹ advocated the use of bicarbonate of potash in large doses, thirty grains every two or three hours, at the onset of an attack of influenza, on the theory that the blood, if made more alkaline, would resist the invasion of the micro-organism. His conclusions were that, "if used before the attack it prevents the disease. It destroys the power of the disease within twenty-four hours, generally within four or six hours. The strength is conserved, and the convalescence is short and satisfactory. Sequela are conspicuous by their absence. The death-rate is reduced to a minimum. It has more power over influenza than is exerted by any method of treatment over any other disease. If adopted by the whole profession it would make influenza non-existent in one week. It rests upon a sound scientific foundation."

In a leading article, the *Lancet* of January 23d, says that the last two conclusions may be open to question, but the preceding are statements which no medical practitioner of standing would venture to put forward without good cause. "We may fail to be convinced of his logic, and yet not refuse to accept his facts; and the evident sincerity of his statements, which are supported by the experience of others, and particularly by the personal testimony of a well-known teacher in Edinburgh University, together with the results of the treatment in the wards of the Edinburgh Infirmary, seem to warrant some attention being paid to them."

OBITUARY.—CLAUDIUS M. JONES.

THE subject of this sketch, whose early death occurred at the Massachusetts General Hospital, Sunday, the 24th of January, was born in Worcester, Mass., the 22d of February, 1845. He received his early education and preparation for college in the public schools of Worcester. In 1862 he entered Harvard College, and was graduated in due course in 1866, the third in rank in his class. During the next few years after graduation he taught as a private tutor in Great Barrington. In 1875 he received the degree of Doctor of Medicine from the Harvard Medical School, at the head of his class. He immediately began a service of eighteen months as house-officer in the Massachusetts General Hospital. This completed, he spent two years in study in various cities of Europe. The bulk of his work was, however, done in Vienna. He had the wisdom to prepare himself by study of the German language in Leipzig, before he went to Vienna, to receive the full benefit of his study in the latter city.

In 1877 he began practice in Boston, and the rest of his life was continuously and actively in practice. During this period he was always connected with the Boston Dispensary. At one time he had charge of two districts of the Dispensary with a room at the central office, in addition to his private practice. In late years he enjoyed greatly his service as physician to the Samaritan Hospital.

His personal character and his intellect were of the highest. Entirely self-reliant, he was at the same time modest and unpretentious. His scholarly tastes made intellectual pursuits his delight. He once said to the writer of this sketch that if he could find time he should enjoy following by himself the West Point course in mathematics. When very busy he found time to read some of the Latin classics. He read French as fluently as he spoke German. Though often urged by his friends to take a much-needed

¹ Lancet, Dec. 19.

rest he worked persistently to the end, which came at the age of forty-six.

He had received the highest degrees from the Masonic fraternity.

Correspondence.

SANITATION IN JAPAN.

YOKOHAMA, JAPAN, January 8, 1892.

MR. EDITOR:—Through the kindness of Mr. Nakahama (Japanese Navy) I am enabled to offer you this abstract from "A Summary of the Two Annual Reports of the Central Sanitary Bureau attached to the Home Department of the Imperial Japanese Government for 1888 and 1889," published in Tokyo, 1891.

During 1885 and 1886 the cholera epidemic prevailed so extensively that hardly any part of the country escaped. By this calamity, the attention of the people was called to the importance of sanitation, which was quietly developed in the course of the years 1888 and 1889, free from infectious diseases. Previous to this time, after each appearance of the scourge, measures for inspection and disinfection were taken, but these, being under the control of the local authorities, were incomplete, isolated and wastefully expensive. The central government has, consequently, employed a sanitary engineer to make plans, examine the question of expense, and superintend the work at the demand of subordinate governments. The construction of water-works and improvement of drains and sewers have been begun in every part of the country. This problem has not yet been solved in regard to Tokyo, where the great extent of space makes enormous outlay necessary. The use of wells, surface-drainage, cesspools, etc., is yet very general in Tokyo and throughout Japan. In Yokohama, good water is brought in pipes from a lake in the hills, some twenty miles distant. (It might be suggested that individual domiciliary attention to cleanliness, boiling of the drinking-water, and thorough cooking of food, are good preventives against spreading of infectious maladies.)

May 6, 1889, regulations as to the organization and powers of the examining committee for the practice of medicine were made known by Imperial Decree, examinations being held in Kyoto, Tokyo and Nagasaki. During this year 569 persons passed the examination (27 dentists); 331 graduated in native medical schools and three in foreign medical schools (one dentist); 21 were permitted to practice within a limited region; 1,198 licenses of practice were returned (1,129 of persons who died, and 69 of those retired from the profession). The number of practitioners who were stopped from the practice by a judgment of the Central Sanitary Board, according to Regulations, was 52. For this year, the total number of physicians was 41,405; of midwives 32,111; the number of licensed apothecaries was 517. There are detailed regulations regarding—(1) control of medicine; (2) manufacturers of medicines; (3) druggists; (4) apothecaries; (5) care and sale of poisonous drugs. Physicians yet dispense their own drugs in practice. The ultimate aim, touching this, is to bring about a separation of the work of the dispensing apothecary from that of practitioner; but such change is necessarily slow, because it is an ancient custom that physicians here make their living by sale of medicines; the people also find this way convenient.

In pursuance of the sanitation plan, the various local inspectors were ordered to the Central Office for instruction.

Examination by analysis has shown that native canned goods are liable to adulteration, some specimens of Japanese condensed milk were good, others bad. *Sake* (native wine-whiskey) was found at times to contain salicylic acid. Confectionery occasionally showed red-lead and other injurious ingredients. Some of the investigations have bearing on Medico-legal questions. The number of examinations of food and drink is greater than before, showing the spread of sanitary ideas among the people.

At the Medical Botanical Garden in Tokyo, good results

have been obtained in the culture of a number of medicinal plants—the more important being *papaver somniferum*, *erythroxylon coca*, *atropa belladonna*, *rheum officinale* and *aspidium filix mas*.

Experiments at the Vaccine Farm (under control of Sanitary Bureau) showed that virus could be preserved for 200 days: glass tubes are used, and furnished to native and foreign physicians. Clothing, etc., is subjected to the moist-heat system for disinfection. "Sick-rooms should be cleansed with a strong carbolic-acid solution or lime-milk, the mats and screens, etc., exposed to the sun-light—the rooms being also thrown open to currents of air." Experiments showed the efficacy of quick-lime as a disinfectant for the cholera poison.

The total number of births for the whole population in 1889 was 1,209,910 or 30.17 per 1,000 persons, 26.31 being the average for the previous nine years. The deaths were 816,241 or 20.36 per thousand, 19.37 being the average for the previous nine years.

The report contains several tables giving details of the numerical relation of sex, births, deaths, population, health of the various territorial and political subdivisions, data concerning the investigations at the Vaccine Farm; and vaccinations, with ages.

Typhoid fever has been somewhat prevalent. A bacillus was found in connection with an epidemic of dysentery, "but it cannot be lightly taken as cause of the disease." Vaccination has greatly lessened the number of cases of small-pox.

At the present time, small-pox is so prevalent as to render revaccination of foreigners prudent.

Very truly yours,

F. B. STEPHENSON, Surgeon, U. S. N.

RECORD OF MORTALITY FOR THE WEEK ENDING SATURDAY, JANUARY 23, 1892.

Cities.	Estimated population for 1891.	Reported deaths in week.	Deaths under five years.	Percentage of deaths from

Deaths reported 3,937: under five years of age 1,276; principal infectious diseases (small-pox, measles, diphtheria and croup,

diarrhoeal diseases, whooping-cough, erysipelas and fevers) 547; acute lung diseases 824; consumption 387; influenza 160; diphtheria and croup 234; typhoid fever 112; scarlet fever 98; diarrhoeal diseases 42; measles 14; whooping-cough 14; erysipelas 13; cerebro-spinal meningitis 12; malarial fever 10.

From diarrhoeal disease Chicago 10, New York 7, Philadelphia 5, Cincinnati, Pittsburgh, Springfield and Mableton 2 each; Brooklyn, Boston and Washington 1 each. From measles New York 8, Chicago 3, Philadelphia, Brooklyn and Milwaukee 1 each. From whooping-cough Chicago 4, Fall River 3, Boston 2, New York, Philadelphia, Cleveland, Milwaukee and Newburyport 1 each. From erysipelas New York 6, Chicago 2, Philadelphia, Brooklyn, Cleveland, Pittsburgh and Lowell 1 each. From cerebro-spinal meningitis Chicago 6, New York 3, Brooklyn, Boston and Washington 1 each. From malarial fever Brooklyn 6, New York 2.

In the thirty-three greater towns of England and Wales with an estimated population of 1,057,736, for the week ending January 16th, the death-rate was 33.0. Deaths reported 1,057,736.

The death-rate ranged from 14.6 in Huddersfield to 57.0 in Portsmouth; Birmingham 20.0, Gateshead 35.3, Hull 25.7, Leeds 25.1, Leicester 17.1, Liverpool 42.0, London 40.0, Manchester 26.6, Newcastle-on-Tyne 31.5, Nottingham 22.5, Preston 22.5, Sheffield 20.3, Sunderland 25.5, West Ham 33.6, Wolverhampton 44.1, Bradford 15.7.

METEOROLOGICAL RECORD.

For the week ending January 23, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 23, 1892, TO JANUARY 29, 1892.

CAPTAIN HENRY G. BURTON, assistant surgeon, U. S. Army, having been found incapacitated for active service by an Army Retiring Board, is granted leave of absence until further orders on account of disability.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 30, 1892.

A. M. D. McCORMICK, passed assistant surgeon, detached from Receiving-ship "Minnesota," and to the U. S. S. "Charleston."

GEO. H. BARBER, assistant surgeon, detached from the U. S. S. "Charleston" and to the Receiving-ship "Minnesota."

A. G. CARELL, passed assistant surgeon, detached from the U. S. S. "Newark" and ordered to the U. S. S. "Kearsarge."

JAMES STOUGHTON, assistant surgeon, detached from the Naval Hospital, Norfolk, Va., and ordered to the Training-ship "Portsmouth."

M. S. GURST, assistant surgeon, detached from Navy Yard, Norfolk, Va., and to the Naval Hospital, Norfolk, Va.

SOCIETY NOTICES.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT, SECTION IN OBSTETRICS AND GYNECOLOGY.—A regular meeting will be held at 15 Boylston Place, Wednesday, February 10, 1892, at 8 o'clock P.M.

Dr. Malcolm Storer will read on "The Radical Treatment in Certain Cases of Grave Accidental Concealed Hemorrhage." Discussion on "Pathology, Prophylaxis and Treatment of Perpetual Eclampsia," opened by Drs. A. D. Sinclair and Edward Reynolds.

GEORGE HAVEN, M.D., Secretary.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A regular meeting of the Society will be held on Monday, February 8, 1892, at the Medical Library, 19 Boylston Place, at 8 o'clock P.M.

Papers: Dr. J. C. Warren, "Operative Treatment of Goitre"; Dr. A. Condie, Jr., "Three Cases of Tuberculosis of the Palate."

The Society is reminded that this is the last meeting of the season at which new members can be proposed.

G. SMITH, M.D., Secretary.

THE EIGHTH ANNUAL MEETING OF THE FIFTH DISTRICT BRANCH OF THE NEW YORK STATE MEDICAL ASSOCIATION will be held in Brooklyn, on Tuesday, May 24th, 1892. All Fellows desiring to read papers will please notify the Secretary, E. H. Squire, M.D., P. O. Box 94, Brooklyn.

RECENT DEATHS.

CHARLES P. PENROD, M.D., Ph.C., M.M.S.S., died January 31st, aged 31. He received the degree of M.D. from the University of Michigan in 1881, and of Ph.C. in 1883. He came to Boston in 1884, as Professor of Materia Medica and Botany at the Massachusetts College of Pharmacy. He was also Professor of Microscopy and Dental Histology at the Boston Dental College. He was a fellow of the American Association for the Advancement of Science, and a member of the convention for revising the United States Pharmacopoeia in 1890.

HOWARD SMITH, M.D., of New Orleans, died January 30th, aged sixty-nine. He served as a surgeon in the Confederate Army and had control of the entire medical service of the Mississippi department. He afterward filled the chair of materia medica in the New Orleans School of Medicine.

WILLIAM H. H. MASON, M.D. (Dart. 1843), of Montenborough, N. H., died January 26th, aged seventy-four. He had served in the State House and Senate, on the Constitutional Convention and the State Board of Agriculture.

LUMAN H. LUCE, M.D. (Bowd. 1859), M.M.S.S., of West Tisbury, died January 30th, aged forty-six. He was the author of several articles on the climate and history of Martha's Vineyard, as well as on different medical subjects.

HAROLD W. SHOVE, M.D., of Woodbury, Conn., died January 26th, aged sixty-five years. He graduated from the Yale Medical School in 1863, and during the war served as surgeon in the navy.

CHARLES A. SAYTORY, M.D. (Dart. 1836) M.M.S.S., of Lowell, died February 2d, aged seventy-eight. He had been three times President of the Middlesex North District Medical Society.

SIR GEORGE EDWARD FAGET, M.D., F.R.S., died in London, January 29th, aged eighty-two. He had been President of the British Medical Association and of the General Medical Council of the United Kingdom. He was made Regius Professor of Physics at Cambridge in 1872.

ALFRED CARPENTER, M.B.C.S., L.S.A., Examiner in Public Health in the Universities of London and Cambridge and the author of several works on different sanitary subjects, died in London, January 27th, aged sixty-six.

BOOKS AND PAMPHLETS RECEIVED.

Thirty-sixth Annual Report of the Trustees of the Northampton Lunatic Hospital, for the Year ending September 30, 1891.

Water as a Local Anesthetic—Its Discovery American and not German. By Robert H. M. Dawbarn, M.D., New York. Reprint. 1891.

LABOR COMPLICATED BY 'PROLAPSED TUMORS.'

BY EDWARD REYNOLDS, M.D.

CASE I. On February 5, 1888, I was asked by Dr. Lamb, of Arlington, to see Mrs. F., who had at that time been in labor thirty hours. The patient stated that for many years she had had occasional attacks of sharp pains in the right iliac fossa, and had been treated for ovaritis by several different physicians.

Her first pregnancy was entirely normal, except for a somewhat unusual size of the abdomen, which at seven months corresponded to the usual size at term. Labor set in spontaneously at that time.

On vaginal examination, the finger encountered a hard, smooth, elastic mass almost filling the pelvis and lying between the vagina and rectum. No change had been noticed in her condition from the beginning of labor till the time of my arrival. The os uteri had not been reached. I succeeded in finding it some distance above the upper edge of the symphysis pubis, there being barely space to pass the finger between the symphysis and the tumor. The new growth was not connected with the cervix, and so far as I could judge, was not affected by the tolerably free motion of the cervix, which it was possible to effect by the combined motion of both hands. It was very slightly, if at all, movable. Its consistency would have accorded well with the supposition, either of a hard elastic solid, or of an extremely tense cyst.

After nearly an hour's taxis under ether, I succeeded in raising the tumor so far that two fingers could now be passed between it and the pubes, but entirely failed at any further progress. After waiting three hours, I found that the elevation which had been gained had not been lost, but no more had occurred. Temperature was then 101.5°, the pulse 90; a rise of two degrees in the temperature and of fifteen beats in the pulse since I first saw her.

The pains failing, the mouth and vagina being dry and hot, I again etherized, and after about half an hour of taxis, raised the tumor sufficiently to permit the passage of the hand between it and the anterior pelvic wall; but my utmost efforts failed to gain more than this.

The condition of the woman being such that further delay was very distinctly inadvisable, I passed the hand by the tumor and found that the os was about the size of a ten cent piece, but so extremely soft that its manual dilatation to a size which admitted the fist was easily accomplished in less than two minutes. The child's head rested against the upper surface of the tumor. It was readily turned and extracted, the operation consuming but five minutes from the time when the fingers entered the os until the delivery of the head through the vulva.

I had anticipated considerable difficulty in bringing even a small head past the tumor; but after the extraction of the shoulders I was surprised to find that the head was in the pelvis. The child was not asphyxiated.

Dr. Lamb readily expressed the placenta, while I was busy in wrapping up the child at the other side of the room. It weighed about four and one-half pounds, and died within a few hours.

On my return, I made a vaginal and bi-manual examination to ascertain the condition of the tumor, but, to my surprise, entirely failed to find it. Indeed, after making what I considered a careful palpation of the abdomen, I was equally at a loss to find any evidence of its presence. I was therefore inclined to believe that the tumor had been an ovarian or parovarian cyst, which had ruptured during the extraction of the child; and expressed the opinion that the after-history of the case would depend on the contents of the tumor.

I did not again see the patient until the eighth day, when I learned that her convalescence had been entirely uneventful, except that the temperature had been somewhat high at night, though normal in the morning. There were no special symptoms to account for this temperature, except considerable nervousness, some pain in the right iliac fossa, and an indefinite resistant mass in the same situation. This mass gradually dissolved and disappeared, and the patient made a complete recovery.

It was supposed that the cyst had been parovarian, and its contents therefore but slightly irritating to the peritoneum, until an examination at the end of some weeks demonstrated the presence of a globular and apparently uniloculated cyst of the right ovary, lying upon the right side of the uterus, and mainly within the true pelvis.

Some months later, the tumor was successfully removed by Dr. John Homans, and proved to be a thick-walled dermoid cyst, filled with the semi-solid material characteristic of this class of growth. It contained a considerable quantity of hair and some calcareous plates. The subsequent history of the case has been uneventful.

CASE II. On July 17, 1891, Mrs. L., was referred to the Boston Lying-in Hospital by Dr. George E. Stackpole. She had had a considerable hemorrhage before entrance, was somewhat blanched, and was still flowing moderately.

In my temporary absence from my office, she was seen by Dr. George Haven, who, however, kindly sent again for me and postponed interference in anticipation of my arrival.

The woman being already so anemic that any further loss of blood seemed likely to be dangerous, I at once put her under ether. Vaginal examination demonstrated the presence of an extremely hard, somewhat lobulated tumor, of about the size of a seven months fetal head, lying between the vagina and rectum, and crowded so far down that the posterior vaginal wall was pressed against the vulva.

The finger passed readily between the tumor and the symphysis pubis to reach the os, which was about opposite to its upper edge. The cervix was somewhat long, and although the os was patulous, we failed to ascertain the cause of the hemorrhage. The tumor was apparently fixed in its position, and both Dr. Haven and I were inclined to believe that we could feel on its anterior and outer aspect a band which passed inward and upward, and which might well have been the Fallopian tube.

Although we felt that a definite diagnosis was impossible, we were inclined to think that the probabilities were in favor of its being a multilocular ovarian cyst. Some minutes of taxis in the lithotomy position proving unavailing, I had the patient placed in the genu-pectoral, where she was held by the house officers,

¹ Read before the Obstetrical Society of Boston, December 12, 1891.

and by Dr. W. H. Prescott, who happened to be present, and kindly rendered much valuable assistance.

After a taxis of fifteen minutes, the tumor suddenly receded above the brim, and passed beyond the reach of my touch. I then passed the finger into the os, and found that the surface of the placenta presented, the insertion being apparently very nearly central. I dilated the os manually, and detached the placenta upon one side until I was able to pass my fingers through the membranes at its edge, when I turned and deliver a very much exsanguinated, still-born child.

The woman made an entirely uneventful recovery. Dr. Haven kindly saw her with me on the day of her discharge from the hospital, when the tumor was found to have decreased to about the size of a six months head, was still of very firm consistency, and somewhat lobulated. We again thought that we could feel a tube extending from the right cornu of the uterus, and becoming lost on the surface of the tumor, and were inclined to adhere to our former diagnosis.

I saw her a fortnight later at the Stamford Street Dispensary for Women. The tumor was again decreased in size, the lobulations were less distinct.

Her next visit was at the expiration of another fortnight; that is, six weeks after delivery. The tumor was then of about the shape of a normal kidney, or perhaps a little larger, firm, elastic and resistant, freely movable, lying habitually at the bottom of Douglas's fossa upon the right side of the uterus.

I did not see her again until the expiration of fully three months from the time of delivery; since when I have seen her at weekly intervals, until ten days ago. The tumor has remained entirely unchanged. It causes no symptoms, whatsoever; but the patient, who is aware of its existence, was extremely desirous to have it removed; and at her request, I referred her to the Massachusetts General Hospital, where she was seen and recommended to enter by Dr. J. C. Warren. Dr. Warren informs me that he recommended her admission for the purpose of more careful examination and consultation before deciding for or against the question of operation. The reasons against the removal of the tumor are, of course, that its presence is causing no symptoms; but, upon the other hand, it seems a question whether the dangers of laparotomy for the removal of a small and movable tumor, furnished, as this apparently is, with a long and slender pedicle, are not less than those which are likely to attend the presence of a tumor in this situation, in the person of a young, married, and presumably fertile woman.

The question of diagnosis is an interesting one. It seems hardly probable that an ovarian cyst would decrease so much in size during the puerperium. The situation of the tumor and the length of its pedicle seem to be somewhat opposed to the diagnosis of a subperitoneal uterine fibroma, while ovarian fibroid, though known to exist, is so rare a disease, that an attempt to establish such a diagnosis, prior to operation, would be decidedly rash.

The subject of the diagnosis and management of intra-pelvic tumors which are first discovered during labor, is one of considerable interest, on which but little is said in the text-books, but which, I think, is, nevertheless, amenable to clear and easily established rules.

For obvious anatomical reasons, the new growth, if intra-pelvic, must necessarily lie behind the vagina;

its presence necessitates a differential diagnosis between a bony tumor of the posterior or lateral pelvic wall, an interstitial or subperitoneal fibroid of the lower portion of the posterior uterine wall, an ovarian cyst, or a cyst of the recto-vaginal septum. Osteoid tumors are to be distinguished from the other forms by the relation which they bear to the rectum, which must necessarily lie, to a greater or less extent, across the anterior surface of any exostosis. Cysts of the recto-vaginal septum rarely attain a very large size, and are differentiated from the other tumors mainly by the absence of any pedicle when the tissues above them are compressed between the two hands; the fingers of one being passed into the rectum behind the tumor, and those of the other employed either in the vagina or through the abdominal wall. In case such a cyst should attain a size which rendered a bimanual examination impossible, its differentiation from a cyst of the ovary would probably be impossible until after the failure of taxis had compelled a resort to operation.

At first sight, it would be thought that the consistency of an ovarian cyst would be so unlike that of a fibroid that no further test would be needed; yet in my limited experience, which comprises only these two cases of ovarian tumor, and but three of intra-pelvic fibroids, the tumor was in each case rendered so tense by the pressure from above, that this test was considered worthless in each of the five cases; and the only evidence which seems to me of real value is the demonstration of the presence or absence of a firm connection between the uterus and the new growth. This is to be made more by the results of abdominal palpation than by vaginal examination; since the region in which the connection, if present, would be found, is almost necessarily beyond the reach of the vaginal finger. If the tumor be a fibroid, motion imparted to the fundus and body of the uterus would almost necessarily affect the tumor; since the rapid growth which is characteristic of fibroids during pregnancy, must almost necessarily involve the conversion of even a slender pedicle in a subperitoneal fibroid into an attachment which is, at least temporarily, tolerably firm. The establishment of the diagnosis between these two forms of new growth is of considerable practical importance; since the ultimate treatment which they demand is radically different.

Besides the three cases of fibroids with which I have been personally acquainted, I have knowledge of three others which have occurred in this immediate vicinity. One of these latter cases was subjected to Porro's operation at the advent of labor; the other five were delivered either by normal labor, or by low forceps, after the spontaneous recession of the tumors, in spite of the fact that in each case the size of the latter was such that delivery by any other means than the Cesarean section seemed at first sight impossible.

The explanation of this occurrence is easy. The non-pregnant uterus contains but a small amount of muscular tissue. So, too, uterine fibroids under ordinary circumstances are made up mainly of connective tissue, which is, however, interspersed with a small amount of unstriped muscle; the histological structure of the uterus and the tumor being closely similar.

The pregnant uterus is, upon the other hand, well known to be composed almost wholly of muscular tissue, which is developed during pregnancy. Although I am unable to quote any post-mortem examination of fibroid tumors of the parturient uterus, it seems highly

probable, both from analogy and from the fact of the rapid growth, and altered consistency which the tumors assume during pregnancy, that their structure at term is again so closely similar to that of the uterus at the same time, as to explain the reduction of volume and the recession upward which is observed to occur, as being the effect of a muscular contraction and retraction of the fibres, such as is observed in the substance of the uterus.

It is then my belief, and I think that of most obstetricians, at least in this vicinity, that intra-pelvic fibroid tumors should be left to nature; at least, until the advent of marked exhaustion renders immediate delivery necessary in the interests of the mother; when in the probably somewhat rare case of the failure of retraction on the part of the tumor, abdominal section and the performance of Porro's operation would undoubtedly be indicated.

With prolapsed ovarian tumors, upon the other hand, no such result can be expected. The tumor must either be raised above the brim of the pelvis by properly directed taxis, or else the delivery can be effected only by the employment of some cutting operation. Taxis must consist of upward pressure upon the lower surface of the tumor through the vagina and rectum, or through both combined. Its successful performance usually requires the administration of ether, and is greatly helped by the assumption of the knee-chest position, as was apparent in my second case; though it was also evident to all who were present that the maintenance of this position in an etherized woman would necessarily require an amount of assistance which would often be obtained with difficulty in private practice. The advantages of the position are, however, so great, that I should be inclined to make strenuous efforts to obtain it in any future case, no matter how situated.

Taxis should be persistently employed for as long a period as seems possible without undue exhaustion of the patient; and if unsuccessful, should be repeated at intervals, until the appearance of the familiar indications which demand immediate delivery.

If at this time a final effort at taxis should prove unavailing, three courses are open to the attendant; namely, laparotomy for the performance of the Cesarean section and the removal of the tumor, aspiration of its contents per vagina, and vaginal ovariotomy.

Vaginal ovariotomy, that is, the incision of the posterior vaginal wall, the evacuation of the tumor, its removal through the incision, and the ligature of its pedicle, would probably under these circumstances become a tolerably easy operation. It is, however, rendered inadvisable by the great vascularity of the vaginal wall during parturition, and by the liability of extension of the incision into undesirable localities by laceration during the subsequent delivery; in addition to which we must still deprecate the entrance of lochia into Douglas's fossa, which must necessarily follow, and which would certainly increase the dangers of the case; though in the light of recent experience, it is probable that under aseptic conditions, this danger is much less than is generally supposed, the more especially as the situation of the incision would necessarily insure the best of drainage.

Aspiration of the cyst through the vaginal wall is a measure which, in these days of successful laparotomy, need hardly be considered. It would hardly be likely

to result in the complete evacuation of any but a unicocular parovarian cyst, since the multilocular character and viscid contents of a true ovarian cystoma, would almost certainly frustrate the purpose of the operation; and it is attended by very great risks of serious peritonitis.

The Cesarean operation, when performed before the advent of really serious exhaustion, and in the absence of visceral disease of the mother, has yielded of late years so very high a proportion of successes, that it is probable that it should be unhesitatingly adopted in any case in which taxis fails to remove the obstacle. Its prognosis would in all probability be but little complicated by a simultaneous ovariotomy; but, should the condition of the patient forbid any prolongation of the operation, this could be left for a second laparotomy.

SO-CALLED SPONTANEOUS COMBUSTION.¹

BY R. H. HARTWELL, M.D., AYER, MASS., *Medical Examiner.*

On the 12th day of May, 1890, while making a professional call in the outskirts of the town, I was summoned into the adjacent woods by a messenger, who stated that her mother was "burned alive."

Hastily driving to the place indicated (about four rods distant) a human body was found in the actual state of conflagration. The body was face downward; the face, arms, upper part of the chest and left knee only touching the ground; the rest of the body was raised and held from the ground by the rigidity of the muscles of the parts. It was burning at the shoulder, both sides of the abdomen and both legs. The flames reached from twelve to fifteen inches above the level of the body. The clothing was nearly all consumed. As I reached the spot, the bones of the right leg broke with an audible snap, allowing the foot to hang by the tendons and muscles of one side; those of the other side having burned completely off. Sending my driver for water and assistance, I could only watch the curious and abhorrent spectacle, till a common spading fork was found with which the fire was put out by throwing earth upon it. The flesh was burned from the right shoulder, exposing the joint, from the abdomen, allowing the intestines to protrude, and more or less from both legs. The leg bones were partially calcined. The clothing unburned consisted of parts of a calico dress, cotton vest, woollen skirt and thick, red, woollen undergarment.

The subject of the accident was a woman, forty-nine years of age, about five feet five inches in height, and weighing not far from one hundred and forty pounds; of active habits and nervous temperament. A wife and mother, she was strictly a temperate person, accustomed through life to hard work, one, who in addition to her household duties, went out washing and cleaning, besides doing a good share of the work in a large garden. On the fatal afternoon, she had — as the place showed — been clearing a lot of stumps and roots, and had set fire to a pile of roots from which it had communicated to her clothing, or it had spread into the woodland and had set fire to the clothing during her endeavors to stop it. The body lay about two rods from the burning pile. As proof that the flesh burned of itself, and nothing but the clothing set it afire, it may be stated that the accident occurred

¹ Read before the Massachusetts Medico-Legal Society.

after a rain; that the fire merely skimmed over the surface of the ground, not burning through the leaves; that there was nothing but charred leaves under the body; that her straw hat which lay several feet distant was simply scorched; that the wooden handle of the spade was only blackened.

The above case is interesting in several particulars. It is the first recorded case in which a human body has been found burning (that is, supporting combustion,) by the medical attendant. It differs from nearly all of the recorded cases, in that it occurred in a person in middle life, not very fat, and not addicted to the use of alcohol. It is interesting in a medico-legal sense. It proves that under certain conditions—conditions that exist in the body itself—the human body will burn. We have abundant proof in the many recorded cases of so-called spontaneous combustion (seventy-three are chronicled in medical literature) that the body has been more or less completely destroyed by fire, under circumstances that show that it will support combustion, and this has given rise to the belief in the spontaneous origin of the fire.

Up to the first part of the present century, the belief in spontaneous combustion was almost universal. Dr. Ogston, professor of medical jurisprudence in University of Aberdeen, in an able article in the *British and Foreign Medico-Chirurgical Review*, 1870, says there cannot be the least doubt that the weight of authority is in favor of spontaneous combustion, or at least, increased combustibility.

Of fifty-four writers on the subject, thirty-five have expressed an opinion. Of these, five are skeptical, Drs. Caldwell, Casper and Taylor and Chemists Bischoff and Liebig; three believe in increased combustibility, Dupuytren, Stillé and Guy and twenty-seven (including many illustrious names) believe in spontaneous combustion.

Dr. C. A. Stockwell, in the *Therapeutic Gazette*, March, 1889, page 168, in a lengthy article, carefully reviews many of the reported cases, and while neither admitting, nor denying spontaneous combustion, the paper appears to defend its possibility.

We know how quickly decomposition sets in, in certain cases without apparent cause, in well authenticated cases even before death takes place.

Sir William Gull, in London *Medical Times*, April, 1885, mentions a case of sudden death of a man of intemperate habits. The following day though cool, while there were no signs of ordinary combustion, the body was remarkably distended, and gas from punctures made in the skin burned like carburetted hydrogen. By the actual contact with fire, combustion of the body, more or less complete, might have taken place in this case.

The account of the mysterious death of Mr. Krook in "Bleak House," "call the death by any name your Highness will, attribute it to whom you will, or say it might have been prevented how you will, it is the same death eternally, inborn, inbred, engendered in the corrupted humors of the vicious body itself, and that only spontaneous combustion, and none other of all the deaths that can be died," calls forth this explanation from Mr. Dickens:

The possibility of what is called spontaneous combustion has been denied since the death of Mr. Krook, and my good friend Mr. Lewes, quite mistaken (as he soon found) in supposing the thing to have been abandoned by all authorities, published some ingenious

letters to me at the time when that event was chronicled, arguing that spontaneous combustion could not possibly be. I have no need to observe that, I do not wilfully or negligently mislead my readers. Before I wrote that description, I took pains to investigate the subject. I do not think it necessary to add the recorded opinions and experiences of distinguished medical professors, French, English and Scotch; contenting myself with observing that I shall not abandon the facts until there shall have been a considerable spontaneous combustion of the testimony on which human occurrences are usually received."

"The opinion of Stillé and Wharton on this subject is interesting. Admitting that the phenomena of spontaneous combustion, so-called, are incongruous with the laws of combustion, so far as they are known, it does not follow that we should reject as unworthy of belief, the many curious and authentic facts on record."

"These may be true, although incorrectly accounted for. Indeed, there are many examples of the spontaneous combustion of organic and inorganic matters which chemistry is unable to explain; but the number of cases now known, the uniformity in the description of the phenomena, and of the age and habits of the persons attacked, require us to regard them as scientific facts, yet unexplained."

"We do not hesitate also to affirm that a belief in the actual occurrence of the phenomena referred to (spontaneous combustion) may be entertained without a satisfactory scientific explanation."³

It is difficult to understand how the authorities just quoted could have held such opinions at a time when Levoisier and Davy had shown what takes place during, and what conditions are necessary for combustion, and so shortly after the exhaustive report of Liebig and Bischoff, proving the theory of human spontaneous combustion to be false, and making the statement that in the living body it is impossible, it shows that the belief in the spontaneous combustion of the human body is still extant.

It is not easy for us to comprehend how the human body, having seventy-two per cent. of water and only five per cent. of fat, can support combustion, even when in contact with fire, much less when independent of this; yet, from a review of the facts, we are forced to admit it, while denying the spontaneous origin of fire in the human body.

In all of the cases which have been subject to an investigation, proof has been given that the fire caught from burning clothing or other combustible substance; not by the evolution of heat through the chemical action of their own elements, and therefore not spontaneous. Those which have not been investigated have occurred at such a time, and in such a manner as to admit of an easy explanation of the fire from natural causes.

Much stress has been laid on the more or less complete destruction of the body in these cases, without corresponding combustion of surrounding combustible substances—large holes burned in the floor, partly consumed furniture, and so on, without destruction of the building; but this is not infrequently seen in accidental or set fires in buildings, when the supply of oxygen is small. I have seen a case, in which a woman fell in the night, with a lighted lamp, burning oil from which set fire to, and burned through the

³ Medical Jurisprudence, pages 880 and 815.

straw matting and floor. The woman was found in the morning burned to death, as she fell, but the fire had gone out of its own accord. Nearly all of the cases reported have been women advanced in life, very fat, and accustomed to imbibe large quantities of alcohol in some form, and supposed to burn more readily on that account, but it has been found that tissues soaked in alcohol do not burn more readily than others.³

The well-known fact that the consumption of alcohol aids the deposition of fat in the human body⁴ is the probable cause of the more frequent occurrence of combustion in these subjects.

Professor Ogston, in paper mentioned, relates a case in the experience of his father, in which so much alcohol existed in the blood that the serum in the ventricles of the brain caught fire and burned from a lighted match, and he has seen in a death from alcohol poisoning, the smell so marked in the ventricles of the brain that it was possible to ascertain the nature of the beverage used.

He also mentions the experiments of Dr. Beveridge, Pathologist of the Royal Infirmary at Aberdeen, in relation to the combustion of human flesh. He found that when a section having no fat, like muscle, is placed next to the flame, the charring which results is slow, while with the cutaneous surface the cutis is speedily destroyed, and cracking permits liquefaction and flowing out of the subcutaneous fat, which taking fire, quickly reduces it to the condition of a black, greasy substance, resembling cinder. Soaking in alcohol makes no difference as to result, neither accelerating or retarding it. First the alcohol is burned, then the tissue, as if no alcohol had been present.

The number of recorded cases of so called spontaneous combustion is too large, the reliability of the witnesses and reporters too great for us to deny that many bodies have been burned more or less completely after the simple ignition of some combustible substance in contact with the body; yet we know that ordinarily it is very difficult to burn the human body. This is seen in the length of time required to consume the bodies of persons burned at the stake, and in the partly consumed bodies of the victims of accidental fires.

In the celebrated Countess Goerlitz case, in which Stauff was tried for murder, experiments were made by Dr. Graff, for the purpose of ascertaining the amount of heat necessary to effect equal destruction of the body, as was observed in this case, the result of which was, that more than one hundred pounds of wood were required to produce even partial combustion of a human body.⁵

Of the forty-five cases of spontaneous combustion, cited by Dr. Frank, of Berlin, in an article published in 1843, it is only assumed that three took place without the immediate presence of fire, and Liebig shows that these cases are wholly unworthy of belief, and adds in relation to the claim of writers that excess of fat and the presence of alcohol in the body bring about an abnormal condition of easy combustibility, "that hundreds of fat, well-fed brandy-drinkers do not burn when by accident or design they come too near a fire."

From an analysis of all the cases on record up to

1851, Liebig arrives at the conclusion that the great majority agree in the following points:

"They took place in winter. The victims were brandy-drinkers in a state of intoxication. They happened where the rooms are heated by fires in open fireplaces and by pans of glowing charcoal, in England, France and Italy. In Germany and Russia, where rooms are heated by closed stoves, cases of death ascribed to spontaneous combustion are exceedingly rare. It is admitted that no one has ever been present during the combustion. None of the physicians who collected the cases or attempted to explain them, have ever observed the process, or ascertained what preceded the combustion. It is also unknown how much time had elapsed from the commencement of the combustion to the moment when the consumed body was found."⁶

The only reasonable and intelligent explanation of the cases of so-called spontaneous combustion is, that human bodies occasionally possess increased combustibility by reason of an unusual deposition of fat, and that age and spirit-drinking are factors only so far as they aid in fat accumulation. Combustibility exists not in the same degree however, even in fat people. This can be accounted for on the supposition that fat, especially when it exists in large amount, occasionally has lowered vitality — more fat globules and less tissue than normal, thus furnishing more fuel for combustion. We know that the gross appearance of some fat warrants this assumption.

We are told by butchers that in some animals — usually the old and very fat — the fat is harder and has a granular appearance, and in extracting the fat from such, much less residue remains.

In the spontaneous combustion of mineral and organic substances (except that resulting from the action of strong acids, which is immediate), the action is slow, the process before combustion being that of heating from simple oxidation or fermentation.

If we are to admit the possibility of human spontaneous combustion, we can only do so on the supposition that it is a slow process, one of increasing heat passing into combustion. There is no account of this intermediate state ever having been observed, nor has exhumation of the body showed the results of spontaneous combustion. The record of reported cases is that the body is found more or less consumed, having been seen alive only a short time before.

That inflammable gases may be generated from rapid or slow decomposition of the body is possible; but that spontaneous combustion is a mode of death, as was once believed, is not possible, and there can be no such thing as human spontaneous combustion taking place after death, while combustibility must be admitted.

INTERNATIONAL CONGRESS OF DERMATOLOGY. — In connection with the second congress to be held in Vienna, in September, there will be an exhibition of all objects relating to the skin, such as scientific works, drawings, photographs, anatomical preparations, microscopes, instruments, and pharmaceutical preparations. The Minister of Finance has agreed to allow all articles from foreign countries intended for this congress to come in free of duty.

OBSERVATIONS ON ALBUMINURIA IN SCAR-LATINA.

BY JAMES W. DUDLEY, M.D.,
Medical House-Officer, Boston City Hospital.

FOR a long time scarlatina has been known to be a disease peculiarly liable to renal complications and sequelæ. But only within a comparatively short time has it been considered incumbent upon a careful physician to watch the urine before any manifestations of renal trouble, such as œdema, had occurred. It is now a common practice to examine the urine frequently, not only during the latter part of the disease when severe renal complications are most apt to occur, but also during the earlier part, with a view of recognizing at once any threatening trouble on the part of the kidneys and of averting it if possible.

At the Boston City Hospital it is customary to have the urine of every patient with scarlet fever examined at least every other day from the beginning to the end of the disease. The writer has had the opportunity of doing a considerable amount of this work and has found the results, although made up of rather minute and perhaps somewhat trivial details, yet, it seemed to him, of sufficient interest and importance to record. To the results of the examinations which have been made by the writer have been added the results of the examination of the urine from enough other cases to make a total of one hundred urines examined from the beginning to the end of the disease. It is the aim of this paper to compare the results of these examinations with a view of determining, *first*, the frequency and importance of the albuminuria which sometimes occurs early in the course of scarlet fever, and *second*, the character and frequency of nephritis, with such other facts bearing upon the subject as have been observed by the writer. The slight evidences of kidney irritation spoken of by some authors as *renal catarrh*, which are said to occur without the presence of any albumen in the urine are not generally considered to have any clinical importance and the writer has thought it unnecessary to regard any urine as abnormal unless it contains enough albumen to be appreciable by the common heat test. Most of these urines were examined by the nitric acid test, but the results were confirmed in many cases by the heat test. The term *renal catarrh* has been applied in this paper to a slightly different condition from that referred to above. It should also be said that the urines examined were from *all* the cases during a number of consecutive months, no selection or omission of cases having been made.

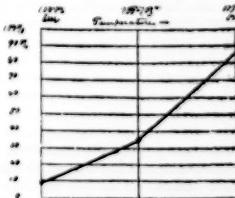

Of the total number of patients with scarlet fever in the hospital during the period covered by these one hundred cases, three died before any specimen of the urine could be obtained. In the following statistics these three cases therefore are omitted as it is of course impossible to say whether there was albuminuria or not. In each of these fatal cases where urine could not be obtained the temperature was high, the lowest being 103° , the highest 104.2° . Cases with suppression of urine in each instance ended fatally.

At some time during the progress of the disease albumen can be found in the urine in about one-half the cases. Out of the 100 there were 49 in which there was found albuminuria to a greater or less degree, 51 being free from albumen from first to last. By far the most common time for the occurrence of

this phenomenon is in the early part of the disease, when the temperature is highest, but high temperature alone cannot account for the presence of albumen as it was noticed in some cases where the temperature was uniformly low. On the other hand a high temperature was not in all cases accompanied by albumen in the urine. Out of 21 cases in which the temperature was 103° or more at entrance (the rash being on the average in its second or third day), 17 cases had albumen, four cases did not; that is 81% of all cases with a temperature of 103° or more, had an appreciable amount of albumen in the urine during the high temperature. This would seem to show that the early albuminuria was, to a certain extent, dependent upon high temperature, or that the too high temperature and albuminuria, have a common cause. We know that in other diseases with high temperature albumen is frequently present in the urine during the height of the fever, and that it should be so in scarlet fever when the same condition is present is not surprising, and in the majority of cases no other explanation seems necessary.

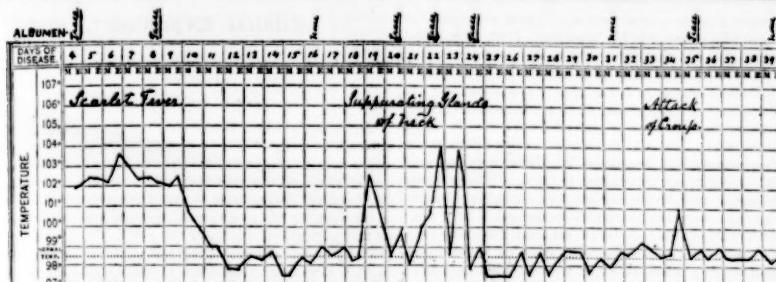

Whatever the cause of the fever, adults are more easily influenced by high temperature than children, and accordingly in this series of cases it was found that in case of all the adults 20 or more years of age who had a temperature of 103° or over (six in number) albumen was present during the height of the fever. In four of these six, the albumen disappeared as the temperature declined without any evidence of nephritis; in the urine of two there were found a few hyaline and granular casts, and in none did the albumen at any time exceed a trace in amount. All of these cases did well.

Dividing the whole number of cases into three divisions according to the height of the temperature at the period of efflorescence, and estimating the percentage of cases having albuminuria in each of these divisions, the same result is obtained, namely, that as a rule, the higher the temperature the more frequent is the albuminuria. This may be seen in the following tracing:

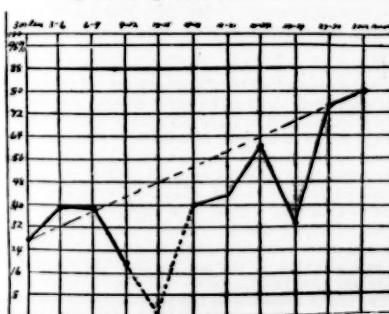

Eight and seven-tenths per cent. of all cases having a temperature of 100° or less had albuminuria; of those with a temperature of 100° to 103° , 36%; while of those with a temperature of 103° or over, 86%. Early albuminuria seems therefore to be, if not the result of high temperature, at any rate an almost normal accompaniment of it and of no prognostic value as regards the subsequent course of the case.

The apparent dependence of albuminuria on temperature in scarlet fever, may be seen in the accompanying chart. The cause of the rise in temperature was a different one at each elevation, but in each instance there was temporary albuminuria. It is not

improbable, however, that the kidneys were in such a condition that their function was easily deranged by a rise in temperature although no serious renal trouble was threatening.

Early albuminuria appears to be more common in adults, whatever the temperature, than in children. Twenty-seven out of the 100 cases were in persons twenty years of age or over, and in 56% of these there was early albuminuria. Of those adults having a temperature over 100°, 75% had albumen, and as stated above, all the adults with a temperature of 103° or over, presented it. Taking the whole 100 cases according to the age of the patients, we find on the whole a pretty steady increase in the proportion of cases with albumen, as the ages of the patients increase. The percentage of cases presenting albuminuria at different ages is graphically shown in the following curve, the horizontal lines marking the percentage of cases with albumen, and the vertical lines the ages of the patients.

Strange to say, there was but one case between the ages of twelve and fifteen, and that case had no albumen. The drop of the curve at that point, therefore, indicates nothing. The cases occurring between the ages of nine and twelve were, with one exception, cases with a low temperature. Those between twenty-four and twenty-seven were also, with one exception, of lower temperature than the average for adults. Albuminuria seems, therefore, to be of much more common occurrence in adults than in children. This cannot be due to albumen being detected in adults as the result of a better appreciation of any change in

the general condition, and attention therefore being directed toward the kidneys, because *all* the urines were examined with equal frequency. It must be taken as a fact, probably due to the greater ease with which children always endure high temperature. It is difficult to see *a priori* why the scarlatinal poison should not affect the kidneys to an equal extent in children and adults, and if the albumen be due to the specific action of the poison on the kidneys, why it is not as common in children as in adults. It must be said, however, that there were a very few cases where there was albuminuria at various times during the progress of the disease not dependent upon high temperature, and apparently to be explained in no other way than as the result of the action of the scarlatinal poison on the kidneys. The writer is not able to say whether some of these few cases may not have had some evidence of renal catarrh, such as casts, which were overlooked, or have occurred as a result of passive congestion of the kidneys from some abnormal condition of the heart, but no case of the sort was noticed. That renal desquamation is not necessarily a predisposing cause of albuminuria is shown by the fact that in two cases, at least, the albumen present during the high temperature cleared up the day that desquamation began.

Albuminuria seems to be rather more common in males than in females. Twenty-three out of the 43 males had albumen in the urine at some time; that is, 53% of the males. Of the 57 females it was found in 27, or 47.4%. The difference between the sexes in this regard seems, however, too small to be of any special significance.

Over-crowding and poor ventilation are said to be fertile causes of scarlatinal albuminuria.¹ It is difficult, however, to see how this cause can have operated in the cases under consideration. The wards are new, very well ventilated, and at no time during the period covered by these cases, contained as many cases as they were designed to accommodate. During the time of the writer's service in these wards, that having the smaller number of patients contained fully as large a proportion of cases with albuminuria as did the other ward which with the same air space, contained the larger number of patients. During the month of March last, when there was an unusually large number of patients in the wards, 43% of the admissions developed albuminuria. During February, also a heavy month, there were 53%. In December, when there were fewer patients, 63%, and in November,

¹ See London Practitioner. 1888, vol. xli, p. 154.

ber, when the clinic was very small, and consequently over-crowding out of the question, 75% developed albuminuria. It therefore seems that over-crowding and poor ventilation have no influence in the production of albuminuria, so far as these cases show.

The question next arises, what are the probabilities of a nephritis occurring as a continuance of the early albuminuria? In adults, where early albumen is most common, this happened in about 14% of all cases. In children it occurred in 20%. These cases of nephritis were of the mildest type in half the cases, and in none were they of a serious nature. The variety of nephritis which is to be especially feared, generally comes later, and does not so far as these cases show, arise as a continuance of the early albuminuria. A temporary nephritis, whose only sign is a few granular and hyaline casts in the sediment, is not to be regarded as a serious trouble. The cases having this variety of nephritis, which might be spoken of clinically as a renal catarrh, in most instances do well, and it is not uncommon for this condition to be present at varying intervals during a considerable part of the illness, without giving the least evidence of its presence, so far as the symptoms, or the appearance of the patient, or the termination of the disease, is concerned. The presence of casts in the sediment indicates some abnormal condition, which, if slight, is generally considered in scarlet fever to be of a catarrhal nature because of the slight pathological changes usually found *post-mortem*, and the frequent epithelial cells from the renal tubules almost invariably found in the sediment. Clinically, at any rate, it does not seem possible in every case to draw a line of distinction between this mild catarrhal condition and a real active nephritis. All varieties and combinations of abnormal urinary elements may be found. The most common variety observed in this series of cases was that containing a trace of albumen (sometimes a very faint trace) and a few hyaline and granular casts, with an occasional leucocyte and a few renal epithelial cells. It is this very mild form of renal affection which has been spoken of above as renal catarrh. Another combination observed was hyaline and granular casts and a few blood globules, with a trace of albumen; another, hyaline and epithelial casts, free blood and trace of albumen. All degrees were found between these and the severe and typical parenchymatous nephritis having a large amount of albumen, $\frac{1}{2}$ to $\frac{1}{2}\%$, free blood and renal cells with hyaline, granular, epithelial and blood casts. What is true of the albumen and sediment is also true of the specific gravity, daily quantity and appearance of the urine. In fact, scarlatinal nephritis cannot be said to have any type of its own, and the only practical criterion which we can make as to the presence of nephritis, seems to be the occurrence of casts of one variety or another in the sediment of a urine containing albumen.

(To be continued.)

PRESERVATION OF MEAT FOR TEN YEARS. — A gentleman in New York has recently tested the result of preserving a turkey in a refrigerator for ten years. This time having elapsed, the fowl was removed from the refrigerator and after being properly cooked was eaten by a party of gentlemen. While putrefactive changes seem to have been entirely absent it was found that the meat was practically tasteless.

Clinical Department.

A CASE OF LAPAROTOMY FOR OVARIAN DISEASE.¹

BY R. A. KINGMAN, M.D.

THE case which it is my privilege to report before you this evening is chiefly of interest by reason of two rather unusual features, the first relating to the shape and location of the principal tumor, thus complicating the question of diagnosis,—the second having regard to the smaller tumor and raising questions of prognosis and perhaps of etiology.

The patient was very kindly referred to me by Dr. Samuel Breck, who assisted in the examination and coincided with me in the diagnosis and in urging immediate operation.

S. K., single, aged thirty-eight years, born in Ireland, three years in this country, during which time she has done heavy work as a hotel laundress. Her father died of "kidney disease." She has suffered from no previous disease of consequence. Two and a half years ago she noticed a small swelling in the lower abdomen at the right of the median line and the whole abdomen seemed somewhat sore. Since that time there has been a gradual increase in the size of the abdomen, which has been more rapid during the past four months.

Her first menstruation appeared at thirteen years of age. At first it lasted a week and was profuse, but after a year it ceased for three or four months and since that time has recurred regularly at an interval of from three to four weeks, lasting four days, without pain, and soiling only four napkins. The last appearance was two weeks previous to the date of the operation. Her appetite has been fair, but the process of digestion is accompanied with occasional discomfort. The bowels are regular. No abdominal pain is experienced, but rather a sense of distension and oppression.

Examination revealed an abdomen distended rather more than at the full term of pregnancy. The abdominal wall, particularly at its lower margin, was markedly edematous. The sense of fluctuation was distinct though not so striking as in ordinary ascites and was absent in the flanks. On each side, just above the iliac spines, was noticed a sense of greater resistance, which yielded before the examining fingers like the head or breech of a child in a uterus containing an excess of liquor amnii. Dulness was complete to a point above the umbilicus, and extended much higher on each side than in the median line. In the flanks there was good resonance.

The uterus could not be felt bimanually; the cervix was crowded somewhat forward, and in Douglas's pouch was felt a rounded mass which was supposed by Dr. Breck and myself to be the sharply retroflexed body of the uterus. The urine had a specific gravity of 1040, was acid, yellowish-gray in color, copious precipitate of urates, no albumen. The legs were edematous at night, but this fact she had noticed for only two weeks.

A diagnosis was made of a multilocular cystic tumor of the ovary, possibly accompanied by ascites, in which case the latter was supposed to be encysted by adhesions. Owing to the marked edema of the abdominal

¹ Read by invitation, before the Obstetrical Society of Boston, December 12, 1891.

wall, malignant growth somewhere within the peritoneal cavity was feared.

After the customary preparation for the two preceding days, the operation was performed at St. Elizabeth's Hospital, on Saturday morning, November 21st, Dr. F. W. Johnson assisting at first, and later Dr. Breck. Asepsis of hands and arms was secured by the use of permanganate of potash, oxalic acid and corrosive sublimate; asepsis of instruments, ligatures, sutures and dressings by exposure to heat.

In incising the peritoneum there escaped fourteen pints of clear amber-colored serum. As the abdominal walls collapsed, there developed a peculiar appearance, two distinct, rounded tumors, elevating the parieties just below the ribs on each side, and strongly resembling a pair of well-developed breasts. On introducing the hand, these were found to be cystic and to be joined at the median line, where they rode the vertebral column like a pair of old-fashioned saddlebags. From this point of union a slender pedicle extended some five or six inches to the left corner of the uterus. The cysts, which were multilocular on both sides, were evacuated and removed, no adhesions being encountered. The contents consisted of a fluid strongly resembling dilute pus, thirty-six ounces flowing out through the canula besides what escaped into the abdominal cavity and around the wound.

In the pouch of Douglas was found a soft papillomatous growth, extending wholly across the pelvis and pressing the uterus forward. At first it was feared this could not be removed, but it soon appeared that the adhesions were neither many nor strong, and that the growth sprang from the right ovary only. It was rapidly separated from its peritoneal adhesions, lifted out of the wound and tied off close to the uterus.

In emptying the cysts part of the fluid found its way into the abdominal cavity, where it was diluted by the ascitic fluid, a part of which had intentionally been left for this very purpose. On the completion of the operation, the abdomen was flushed out several times with hot salt solution, a glass drainage-tube was carried to the bottom of Douglas's pouch and the wound was closed with silver-wire sutures. A dressing of powdered boracic acid, baked gauze and baked cotton was held in place by adhesive plaster and a binder, and she was placed in bed.

She rallied well, had little vomiting and made an uneventful recovery. The first efforts at vomiting caused quite a copious discharge of fluid, slightly tinged with blood, from the drainage-tube, but on sucking out the tube every hour very little was removed. During the night the flow increased so that the tube was sucked out every half-hour. After three days the tube was removed and the same afternoon the bowels moved freely with the help of citrate of magnesia.

Part of the stitches were removed on the eighth day, the remainder on the eleventh day.

Present condition, three weeks after operation: Wound perfectly healed. No pain or tenderness anywhere, patient feeling perfectly well. The uterus is in a position of left latero-version, moderately enlarged. There is a little fulness in Douglas's pouch, not hard nor sensitive, but giving the impression of exudate about the track of the drainage-tube, or of a slight increase of the papillary remains left at site of the severed adhesions. Temperature 98.6°, pulse 70.

The two questions of interest I have already suggested are the only ones I will touch upon, for it is

my purpose to-night merely to report the case with little of note or comment. In connection with the cystic tumor it is to be noted that owing to its broad bifurcation, it so rode upon and held down and back the intestines, that in spite of the presence of a large amount of ascitic fluid there was resonance in both flanks, dulness over the whole front of the abdomen to a point well above the already elevated umbilicus, and absence of fluctuation low down on the sides of the abdomen. In this mass of fluid the floating cysts, buoyed up by the intestines, moved freely under the hand so adding to the difficulty of accurate diagnosis.

But the second and smaller tumor is of far more importance for purposes of discussion. The data easily within our reach concerning papillomatous growths in the pelvis, with infection of the peritoneum, are scarce and not very satisfactory. The general impression is that while not in themselves malignant, they are liable upon the slightest provocation, or even without special cause, to undergo malignant degeneration. Even though, as in this case, the tumor proper can be readily and completely removed, yet the peritoneal adhesions may serve as foci from which proliferation may occur, to be followed sooner or later by cancerous or sarcomatous degeneration. Whether it is better in these cases to scrape the points of infection as clean as possible and promptly close the abdomen, or whether keeping the wound open and packing the pelvis with iodoform gauze offers a better chance of cure by encouraging suppuration and cicatricial starvation of the growth, is a question for consideration. Is the disease bound to return and cause death, or is there a chance of gaining a complete cure? Of the latter, how can we make the result more sure than by the method practised in this case?

The pathologist's report just received this evening from Dr. F. B. Mallory, is as follows:

"A papillomatous mass from right ovary, size of fist; several small cysts present in base; probably a ruptured papillary cystoma. Mass from left ovary contained two large cysts and a number of small ones. Portion of outer wall of large cyst thickened and in places covered with small papillary masses. These were probably originally within a cyst which has ruptured. Inner wall of cyst studded with numerous papillary projections of varying size."

"Microscope showed papillary masses covered with a single layer of cylindrical epithelium. The papillary masses themselves are in some cases very cellular and made up of spindle cells; in others they are more fibrous; the larger proportion, however, are composed of branching cells separated by clear, translucent material, suggesting Wharton's tissue. The papillary masses in many places, on account of their delicacy and manner of branching, resemble chorionic villi."

"Diagnosis — Papillary (myxo-sarco) cystoma."

"Prognosis bad."

THE ALVARENGA PRIZE. — The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, amounting to about one hundred and eighty dollars, will be made on July 14, 1892. Essays intended for competition may be upon any subject in medicine, and must be received by the secretary of the College on or before May 1, 1892. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college.

A CASE OF PAPILLOMA OF THE OVARY AND
FALLOPIAN TUBE.

BY C. M. GREEN, M.D.

THE patient, aged twenty-seven, was first seen in April, 1891; the right tube was somewhat enlarged and tender and there was an endocervicitis of long standing: the ovaries were apparently not enlarged. When seen early in July, before going away for the summer, the patient was generally improved; but the condition of the right tube was unchanged. Three months later, when next the patient was examined, it was found that the right ovary was enlarged to the size of the fist: it was thought by Dr. George Haven and myself that the ovary was cystic, and operation was advised. Dr. Haven kindly performed laparotomy for me November 6th, and to our surprise, when the abdomen was opened, we found a papillomatous mass, the size of the fist, involving the right ovary. Neither the parietal peritoneum, nor adjacent organs were apparently at all invaded: the broad ligament was tied off and the entire growth and the right Fallopian tube were removed.

Dr. F. B. Mallory, of the Harvard Pathological Laboratory, kindly examined the specimen and reported:

"The papillary growth probably originated in a cystoma which has ruptured, and of which the wall has disappeared. There is a very reasonable hope in this case of non-recurrence."

The patient made a non-febrile convalescence until the eleventh day when there was an attack of pain, following a movement of the bowels, with some elevation of temperature: and for several days there was fever, and pain in the right inguinal region. The temperature suggested pus; ether was then given with the expectation of locating the trouble and perhaps aspirating; but examination revealed a hard, non-fluctuating mass to the right of the uterus, as large as the fist nearly. Finding no evidence of abscess, nor, at all events, of pus within easy access, it was decided to wait: the next day, there was a discharge from the vagina of a sero-sanguinous fluid containing thick, white, cheesy material; the mass disappeared and the patient made a speedy convalescence. What this mass, or effusion, was, neither Dr. Haven nor I have been able to assure ourselves.

The points of interest in this case are the rapid development of the papillomatous growth, the unexplained effusion occurring as late as the end of the second week, its complete disappearance, and finally the question of recurrence. Thus far the patient has been quite well, and subsequent developments will be awaited with interest.

Medical Progress.

RECENT PROGRESS IN LEGAL MEDICINE.

BY F. W. DRAPEK, M.D.

PREGNANCY AND DELIVERY; ABORTION; INFANTICIDE.

Unconscious Parturition in a Primipara.—Brunon¹ reports a case of more than usual medico-legal interest. It related to an intelligent, healthy married woman, twenty-two years old, at the end of her first pregnancy. She had a troublesome cough which was attended with

¹ *Jour. de Med.*, April 19, 1891; *New York Medical Journal*, June 27, 1891.

some pain in the lumbar region. This pain increased somewhat but not to a degree to suggest to the woman, or her family, that medical aid was required, but rather that it would be relieved by defecation. She remained an hour in the water-closet, and then went to bed with her lumbar pain decidedly less. An hour and a half later, there was a renewal of the desire to go to stool, with pain in the loins such as she had felt before when constipated. As she rose from her bed and brought her thighs together in the act, she was prevented by an obstruction which, upon examination, was found to be the head of her infant protruding from the vulva. At no time had the question of parturition occurred to her, and her first intimation as to what was going on was when she touched and saw the child's head between her thighs. The patient was a woman of calm temperament and good health and belonged to the cultivated class. There was nothing in her antecedents that would have any bearing upon this nearly painless labor. There was no abdominal colic at any time, there were no terminal expulsive pains, which are usually so severe; in fact, the only evidences of the process of parturition were the lumbar pains, the feeling of weight in the rectum, and the illusory desire to defecate.

Air Embolism.—Hektoen adds a case to the rather limited series of illustrations of sudden death by the introduction of air into the circulation through ruptured uterine veins.² The patient was a woman of nineteen years, married seven weeks before her death, but pregnant in the fourth month. She was in good health, except that she had occasional attacks of headache and vomiting. She went to her bedroom for the alleged purpose of changing her dress. After she had been in the room about ten minutes, the noise of a fall was heard. Her husband at once entered the chamber and found her lying on the floor with her head against the wall; beside her was a Davidson's syringe, a chamber-vessel and a basin of cold water, all arranged in such a way as to suggest that she had commenced to take a vaginal douche or was about to do so. Her husband placed her on the bed and then found that she was dead. All this transpired within twelve minutes.

The autopsy was made twenty-four hours later. There was no sign of decomposition. There was no sign of violence about the external genitals, and there was no blood or other fluid in the vagina. The uterus was enlarged so as to fill the pelvis. The right ventricle and auricle contained bloody froth; the left ventricle was empty. The lungs were congested and edematous. The veins in the abdomen contained interrupted columns of blood and air. Within the cavity of the womb were two or three fluid ounces of blood. At the inferior border of the placenta a separation had occurred to the extent of about three-quarters of an inch. Within this portion of the uterine wall were seen the openings of many ruptured sinuses. The other organs, the kidneys, liver, spleen, stomach, intestines and brain, presented nothing abnormal.

A Case of Infanticide with Rupture of the Spleen.—Coutagne, of Lyons, reports the following instance of rupture of the spleen in an infant.³ A woman, twenty-nine years old, was delivered of a living child on the 17th of September; on the 27th of the same month she threw the child from a wharf, intending that it should be drowned in the river below. It was killed

² *North American Practitioner*, March, 1891.

³ *Bulletin Gen. de Therap.*, September 13, 1891.

by striking upon the edge of the stone wharf-pier, which had arrested its fall. The autopsy discovered some head injuries; but the most important lesion was a rupture of the spleen. In the abdominal cavity were 150 grammes of blood. The splenic region was the centre of a collection of large clots. The spleen was of normal consistence and color; it weighed 17 grammes; on its outer surface, at about the middle, were three large transverse rents, joined by a fourth vertical fissure; two of these lesions involved the entire thickness of the organ, extending through to the capsule on the inner surface. There was a subcutaneous ecchymosis of the size of a small pea, but no other injury to the left hypochondrium. The ribs were intact. The supposition that the injury was the result of a direct blow over the spleen seems to M. Coutagne to have been demonstrated by the small size of the organ, its mobility and its protection under an osseous covering, which in infancy is endowed with special elasticity.

IS A MALIGNANT PUSTULE A DISEASE?

A man living in Iowa had been, for some time before his death, insured against bodily injuries, in a sum not exceeding five thousand dollars, by a Mutual Accident Association of New York City, the condition of the insurance being that the bodily injuries should be the result of external, violent and accidental causes, and not of disease. He had been in Iowa but two months when his death occurred, and a claim was at once made against the company for the full amount of the insurance benefit. It appeared that in some unknown way he became the subject of a malignant pustule on the lip, and that this was the sole cause of the death. He had been a bookkeeper in a meat market, and, later, a clerk in a railroad freight office. Car-loads of hides frequently passed the railroad station where he was employed, and a large number of cattle were slaughtered in the neighborhood: but there was no direct proof that he ever came in immediate contact with the hides or with the animals. Yet it was claimed by the plaintiff, in the suit brought against the insurance company to recover the sum above named, that the pustule from which the insured died was the result of an external injury accidentally received; it was not a disease but an accident. In support of this proposition some elaborate expert testimony was introduced. The leading medical witness stated that malignant pustule is not a disease, in the strict sense of the term, but "a pathological condition of the system," caused by the accidental inoculation of "diseased" or putrid animal matter, infested with bacteria or anthrax bacilli, upon the thick skin of the lip, whence the bacilli multiply and are diffused through the system." The animal virus that produces the sore comes from the hides, hair, wool or flesh of animals suffering from anthrax, and it may be transmitted to human beings by direct contact, or it may be conveyed by insects and implanted upon some exposed part of the body. The witness admitted that there had been some "epidemics" of this "pathological condition" in this country.

The defendant company claimed that the disease which caused the death in the case at issue was a carbuncle; and, in any event, whether it was the result of a carbuncle or of a malignant pustule, the death was by disease and not from accident. In behalf of this view, more expert testimony was taken, Dr. Prudden, the distinguished bacteriologist, being among the witnesses.

The judge instructed the jury that if the cause of the death was a carbuncle, the plaintiff could not recover his claim; but that if it resulted from a malignant pustule, his claim was recoverable. The jury returned a verdict against the company. The case was carried to the Court of Appeals; the judges of this court were divided in their opinion, five of them declaring that the evidence of the physicians called for the plaintiff showed clearly that death from malignant pustule was regarded generally by medical authorities as death from disease; that "accidents" cannot be "epidemic"; and that "a pathological condition," which is not a "disease," offered an insufficient basis for an insurance claim against an Accident Insurance Company; two of the seven judges dissented from this view and held that "the infliction of animal virus by some exterior force or power was a bodily injury effected through external, violent and accidental means."

Lowell, who reports this case,⁴ suggests that if the position of the minority of the judges be correct, in this instance, it would be equally correct if applied to a person who should pass through a hospital where there were cases of scarlet fever or small-pox, and should contract fatal infection thereby. He might go further in his suggestion and include the "accidents" which the contagium of syphilis or the bacilli of tuberculosis or the micro-organisms of other "pathological conditions," generally called infectious diseases, bring about.

PROCREATIVE ABILITY AFTER CASTRATION.

Massazza reaches the following conclusions as the result of some experimental researches undertaken in the laboratory of legal medicine at the University of Pavia:⁵

(1) Castration does not immediately deprive an animal of *potentia coeundi*.

(2) One can find, for some time after removal of the testicles, normal spermatozoa in the efferent ducts and in the seminal vesicles.

(3) These spermatozoa do not always retain their fecundating power.

(4) Only those zoosperms are fertile which preserve their characteristic movements, or which can recover those movements by a special treatment.

(5) If one finds in the liquid withdrawn from the efferent ducts or the seminal vesicles zoosperms with the body detached from the tail, he may conclude that all the spermatic filaments are dead.

(6) The fecundating power of zoosperms found in the seminal passage of animals castrated does not continue more than nine days after the operation.

(7) If one applies to the human subject the results demonstrated in animals, one may conclude that the activity of the zoosperms lasts a short time only, and does not extend beyond the ninth day after castration.

(8) As it is probable that a man who has just been mutilated by castration will hardly feel capable of sexual intercourse during the nine days which follow the operation, the procreative potency of men who have been thus deprived of both testicles may be absolutely denied with confidence.

IS STERILITY A DISEASE?

Mr. Justice Holmes, of Dublin, has made a decree of much interest to medical men to the effect that ster-

⁴ Brooklyn Medical and Surgical Journal, June, 1891.

⁵ La Riforma Medical, February 9, 1891.

rility is not "sickness" within the legal sense. A suit was instituted by a Dublin physician to recover fees to the amount of nineteen guineas for attendance upon the wife of a solicitor. The lady, it appeared, suffered from no other disease save sterility, but anxiously desired a cure for this disability, and sought advice with this object in view, whether with or without the knowledge and consent of her husband did not clearly appear. The physician attended and made many examinations and sundry applications of sponge tents and other instruments, for the purpose of dilating the cervix uteri. The lady's husband refused to pay the gynecologist's bill, on the ground that the treatment of his wife for the cure of sterility was not a "necessary" for which the law required him to pay, and on the additional ground that the medical attendance was without his, the husband's, knowledge or consent. The law laid down by the judge in his charge to the jury was as follows: (1) Every man is bound to provide necessary medical care for his wife in case of sickness. (2) Every husband is liable for payment of fees in case of such sickness, whether he knows of the attendance on his wife or not. (3) But sterility is not a sickness for the treatment of which a husband can be made liable; it does not shorten life, or prevent the discharge of household duties, or cause physical pain. Therefore medical attendance for the cure of such a condition is not a "necessary" within the meaning of the law, and the physician in this suit could not recover the fees charged. It should be added, however, that he could still recover against the separate estate of the wife, if she had any, for "work and labor done," though the "work and labor" might not be legally "necessary" as against the husband.

Reports of Societies.

NEW YORK NEUROLOGICAL SOCIETY.

MEETING of January 5, 1892, the President, DR. L. C. GRAY in the chair.

THOMSEN'S DISEASE.

DR. C. L. DANA exhibited a male patient, thirty-three years of age, who presented the typical phenomena of this disease. The family and personal history of the patient were good. There was no specific trouble, and no previous nervous disturbances. The first symptom noticed was a weakness of the muscles, which came on at the age of seventeen. Three years subsequently it was found that, when the fists were closed, they could not be opened again, voluntarily, for some little time. These conditions had increased until at the present time, the only muscles not involved in the process were those of the thighs and upper arms. The myotonia was most marked in the muscles of the forearms and legs. No contractions of the pillars of the fauces were observed. There were no sensory disturbances. Reflexes were nearly abolished and could only be obtained by reinforcement. There was slight increase of reaction, to the galvanic current but not to faradic. The author felt convinced from very careful tests of the muscles that the phenomena were confined to the muscles themselves and that it was not due to a reflex influence, but that the disease was a purely muscular one.

PERIPHERAL NEURITIS, OR POSSIBLE LESION OF THE POSTERIOR NERVE ROOTS.

DR. W. M. LESZYNISKY presented a patient with the following history: A woman, fifty-three years of age, while trying to raise a heavy weight, injured the shoulder-joint. Neuritis of the brachial plexus developed within a few days. When she first came under treatment nearly six months after the accident, she was suffering from extreme pain and tenderness in the course of the median and musculo-cutaneous nerves. There was no circumscribed paralysis but a general weakness of the entire limb. The pain was relieved by treatment. Within two weeks the entire extremity gradually reached a condition of complete anesthesia, including loss of muscular sense. Subsequently the adductor pollicis and the flexor longus pollicis became paralyzed. This paralysis had disappeared, however, within ten days, and simultaneously, there was a restoration of all forms of sensibility, including the muscular sense, over the thenar group of muscles and the entire thumb, the rest of the limb remaining anesthetic. There was diminished faradic irritability in the thenar, hypotenar and interossei muscles. Any hysterical element could be excluded. He thought the diagnosis rested between a peripheral neuritis affecting the sensory nerve branches, and a possible lesion of the posterior nerve roots.

DR. MARY PUTNAM JACOBI did not see why Dr. Leszynsky was so positive in excluding hysteria as the probable cause of the condition in his case. The distribution of the anesthesia was such as one might expect in an hysterical patient. Because there had been no other exhibition of any recognized symptoms of hysteria, did not exclude the disease in such a case as just presented.

SPASMODIC SCREAMING.

DR. J. A. BOOTH presented a patient aged seventy-three years, a peddler by occupation, who had been under observation in the Nervous Department of the Manhattan Eye and Ear Hospital for the past four years. He had also been a frequent visitor to the various clinics in the city. The patient had enjoyed good health, well up to nine years ago; about that time after one week of great headache, he had an attack of left hemiplegia with disturbance of speech. He was ill in bed fourteen weeks, and during this time had suffered intense and constant pain in the head. The paralysis had gradually improved; the disturbances of speech had disappeared, and he had returned to his business of peddling one year after the attack. Ever since the onset of illness he had had more or less head pain, localized over the right parietal region, and which he had described as appearing in a spasmodic manner shooting up to that portion of the head. The attack was ushered in by a flexion of the ring and middle fingers of the right hand, the other fingers being straight, the whole hand was then rapidly rotated, the attack culminating in a loud scream and the placing of the hand on the right side of the head. He had also complained of not being able to sleep, and his wife had corroborated this statement by adding that he was a nuisance to her and the neighbors by these attacks of screaming at night. These paroxysms could also be brought on apparently, by suggestion, although the speaker had never been able to get the patient under the hypnotic influence. After going over the case carefully, Dr. Booth was inclined to believe that

at the present time the patient was more of a simulator than anything else.

DEBATE ON THE THERAPEUTIC VALUE OF HYPNOTISM.

DR. L. C. GRAY said that his object in calling for such a discussion was to ascertain the consensus of opinion of the New York Neurologists in regard to the value of hypnotism therapeutically. He did not want to hear any historical data on the subject, but the personal experience of those who had given the matter serious attention.

DR. DANA referred briefly to the work of the late Dr. Beard, as being the only contribution made by an American author on this subject. From a long series of experiments that writer was convinced that hypnotism was a real condition and not a myth. He was not able, however, to produce partial states of hypnosis, although he attached some value to suggestive therapies. The speaker had been able to produce complete hypnosis in fifteen per cent. of the cases submitted for experiment, and only a partial state in from thirty to fifty per cent. As to its value as a remedy in any of the known neuroses, it was doubtful if it had any efficacy. There were many therapeutic measures which were so much easier of application and which possessed recognized virtues, that it seemed to the speaker unwise to exchange them for something with such subtle power, and so difficult of control, as was hypnotism. Taken altogether it was a remedy that could rarely, if ever, be used with benefit.

DR. G. W. JACOBI said that he had been through two epidemics of hypnotism. The first, lasting from 1880 to 1884, and the second in 1888. In order to ascertain just what position he occupied in regard to the value of hypnotism as a therapeutic remedy, it was necessary for him to review his work in this direction. From old note-books he had found a record of nine cases marked cured, in which hypnotism had been the remedy. In following out the further histories of these cases, which were of various forms of hysterical neuroses, it was found that in all and every instance there had been relapse of the trouble. This result had no doubt been the cause of the author abandoning hypnotism as a therapeutic agent. While it might possibly be good for some subjects, and for the control of some symptoms temporarily, why should we use a method that was laborious and surrounded by mysticism and charlatanism, when other remedies had to be ultimately resorted to anyway. The only way in which any conclusion could be arrived at in regard to the therapeutic value of hypnotism was by means of statistics, and these, so far, had been more or less unreliable.

DR. VOUGHT described the method of producing hypnotism as employed at the Vanderbilt Clinic. Some bright object was held before the patients' eyes and at which they were told to gaze, while the physician encouraged them to try and sleep. Such means had rarely failed to produce the desired hypnotic condition. In no instance was bad effect observed to follow its use; in some a slight pallor came on, but nothing of further consequence. The therapeutic application of hypnotism was successful in most of the cases, such as neuralgias and persistent pain. The speaker thought that it was to be recommended in this class of cases.

DR. E. D. FISHER said that so far as his experience and personal observation went, he was not favorable

to the use of hypnotism as a therapeutic remedy. He had not, as yet, seen or heard of any permanent successful issue from such procedure. He thought that it might also be a dangerous measure in many cases, especially in certain mental conditions. At any rate, if hypnotism were to be used at all it should be only with the greatest precaution.

DR. J. W. COLLINS has used hypnotism in thirteen cases and was able to report cure in five of these. It was not his practice to use the remedy promiscuously, but when he had decided that the case was suitable for hypnotism he had carried out the system of mental suggestion, and was able to get quite good results from it. While he did not claim that hypnotism was a panacea for all nervous diseases he was satisfied that it possessed therapeutic value in certain cases. He thought that it was a great mistake to say that patients were non-hypnotizable if they did not succumb to the influence in a short time. He had seen the masters in this branch, at work at a patient for one, two and even three hours, in some instances, before they could be brought under the hypnotic influence. He did not want to appear as an enthusiastic advocate for hypnotism, but he was convinced that it had a field in certain psychical conditions and especially in moral perversions. Considering the fact that the present method of dealing with these cases offered but little in the way of cure, there should be no hesitancy in at least giving hypnotism a fair trial and not being satisfied with simply an attempt or two, but persisting until such a condition of the patient was brought about, so that mental suggestion could be responded to. If carried out consistently the author was sure that hypnotism would offer more as a moral educator than any other measure that had ever been advanced.

DR. LESZINSKY thought that the length of time that it took to get the patient under the hypnotic influence was a matter of indifference. As yet, there were no statistics to show the bad influence of hypnotism, but in cases where the author had failed to produce hypnosis the patients had been left in an uneasy, uncomfortable state. He did not think hypnotism by any means devoid of danger. He described the case of a child twelve years of age, whom he had treated for hysterical attacks of laughing and crying. She had improved very much under ordinary attention and finally passed out of the author's hands. Some time subsequently there was a slight return of the trouble and the mother took the child to some one who tried hypnotism, the first attempt being unsuccessful but was persisted in until complete hypnosis was brought about three or four times. From this time on all of the symptoms became exaggerated and when the author saw the patient again she had developed all of the phenomena of hysteria. He felt satisfied that hypnotism was responsible for the deterioration in the nervous tone and the development of hystero-genic zones. It had been two years since he had practised hypnotism. The last patient upon whom he had tried it was suffering from singultus, during the hypnotic state the spasm was abolished; suggestion at this time that the paroxysm would not return when consciousness was restored, proved failure, as the spasm had returned in an aggravated form. As for hypnotism being applicable in insanity it was thought rather doubtful that it could be done at all, for the reason that the degree of concentration necessary could not be obtained in this class of patients.

DR. BOOTH had, during the past four years, made use of hypnotism in twenty-four cases, fifteen females and nine males. Of the fifteen females, ten were easily hypnotized and responded to suggestion, in five no hypnotic effects were produced, although repeated attempts were made. Of the nine male cases six were failures. The histories and treatment of four cases were then read in detail. Case I. A young girl, aged seventeen years, suffering with tremor of the left upper extremity, was hypnotized daily for one week, during which séance, proper suggestion was made. At the end of that time the tremor had entirely disappeared and had not returned a year after treatment. Case II. Hysterical attacks in a girl, aged nineteen years. She was easily hypnotized and was markedly lethargic going into a deep sleep from which it was difficult to arouse her, either by suggestion or stronger measures. Subsequent séances did not produce such marked effects and were successful in lessening the number of attacks. One attack only had occurred during the past year. Case III. Double ptosis. The patient was easily hypnotized and after fourteen séances there was marked improvement. Case IV. Another patient with hysterical attacks, which were ultimately cured by hypnotism.

DR. B. SACHE had not been able to do much with hypnotism, and as yet had accomplished nothing therapeutically. He had tried the method in cases of hystero-epilepsy and where persistent pain had existed for years, in every instance the therapeutic effect was absolutely nil. The only two cases in which a certain amount of benefit seemed to be derived from hypnotism, were of nerve-deafness occurring in two young women. The improvement continued during four weeks in one case, and three months in the other. He thought, however, that hypnotism, as far as any real therapeutic value was concerned, was only a fashion at present and that it would soon be laid on the shelf.

DR. JACOBI described a case which had recently come under her observation, the course of which, possibly bore some analogy to the way in which hypnotism operated upon the nutritive states through some controlling mental emotion. The patient, a woman of emotional characteristics, had complained of severe pain in the shoulder-joint. There was present much swelling and anesthesia. Despite all treatment the condition had increased in severity. After the tenth day hysterical attacks of screaming came on, followed fourteen days after the onset of the trouble, by considerable vomiting of blood. About this time the patient's child had become dangerously ill and had died in a few days. From this time on all her symptoms connected with the shoulder and the general condition had gradually subsided and finally disappeared. Health in a short time was completely restored. The speaker thought this was a clear case of great mental emotion having the power of re-organizing and controlling the nutritive states, as shown in the rapid recovery when the mind was concentrated on the illness and death of the child.

DR. L. C. GRAY had practised hypnotism since 1886 upon hundreds of cases in his hospital wards, but had finally given it up in this class of patients, as he had found that it had a demoralizing influence and that moral control over them was lost by persisting in its use. In some cases where he had tried hypnotism he had found that his patients would leave him and go to some one else. He thought, however, that in the present study of hypnotism we were only on the verge

of a great developmental knowledge of psychical laws which might prove to be of great value. From his experience in the use of this agent as a therapeutic measure he was not able to say in what class of cases or individual case that it would, or would not, be beneficial. If he could draw any deduction he would say, that the hysterical cases offered the best results. No one understood the nature of hysteria any way and there were no conclusive criteria by which hysteria could be diagnosed, but in the symptoms laid down as such, hypnotism had produced some amelioration although relapses had occurred. In functional symptoms such as delusions of fear, fright and timidity and so forth, good results were obtained by hypnotism. In other neuroses such as neuralgias and organic diseases of the nervous system, the benefits were not as good as from other known remedies. The author had never been able to hypnotize an insane patient and in the paranoiac the practice had filled these patients full of delusions. Altogether no good results were obtained in these two classes of patients, but much harm in the latter. There need be no difficulty in hypnotizing patients, if it could not be done in one way it could be done in another. The author had found that where a patient was hard to get under the influence they were apt to sink into coma afterward. He had such a case where the patient when observed some time after being hypnotized was almost in a comatose state and was very ill for the remainder of the day. He had never heard of a death being produced by hypnotism, but did not think it unlikely that it might happen. He would not, however, condemn hypnotism until it had a further and more conscientious trial.

MASSACHUSETTS MEDICAL SOCIETY.
SUFFOLK DISTRICT.
SECTION IN OBSTETRICS AND GYNECOLOGY.

GEORGE HAVEN, M.D., SECRETARY.

A MEETING of the Section was called Wednesday, December 28, 1891, to elect a Chairman and transact such other business as might come before the meeting.

DR. C. M. GREEN was unanimously elected Chairman, and upon assuming the chair said: The history of this section is somewhat interesting. It has had spasmodic meetings at times, and many of the meetings that have been held have been very profitable and satisfactory. I have served myself, as secretary of some of the other societies, and I know how difficult it is to get material for papers, and to find men who are ready to come and talk and bring specimens. I can see no reason why we should not have an active working section in this department. There are other societies in Boston; but Boston is a large city. Other societies do not absorb all the material of the city, and there are a good many members of the Suffolk District who are not members of some of the special societies, so that there is no question in my mind but that there is ample material to make this section a success, provided the members will co-operate with the officers of the Society to make it such. It is very hard for a secretary or presiding officer to go to members and beg them to write a paper, and I hope that the members of the section will be willing to come forward and offer to read papers.

I suppose the meetings will be held once a month. We ought to select the evening for meeting, to-night.

Upon motion of DR. E. W. CUSHING, the section voted to meet hereafter on the second Wednesday of each month.

DR. GREEN: Of course, the work of the section will be chiefly the reading of papers. It has always seemed to me that a good deal of valuable work might be done in the way of discussions. There are a good many members who have not the time to prepare a set paper, but who would be very glad to come and discuss a subject that might be selected. It seems to me that that would be one very profitable method of spending our time; possibly a paper at one meeting, and discussion at another on some broad subject. It is to be hoped that members who have pathological specimens will bring them.

It has seemed to me that the mere presence of the reporter and the fact that whatever one says is to be printed, deters some of us from saying anything. I look upon publication to some extent as being a positive injury to the well-being of medical societies. I have often hesitated from saying something I would have rather liked to say, because I did not want to take the trouble to correct the proof. We need not have anything more appear than we want to, and each member can cut his own remarks out if he does not see fit to revise the report.

DR. E. W. CUSHING: Dr. Price has written me that if this section is organized he will accept an invitation to come here and give us a paper on tubal pregnancy, as he has had over sixty-five cases on which he has operated. It seems to me if we could have subjects for discussion beforehand it might obviate the difficulty of getting papers.

Dr. Cushing then showed a

CANCEROUS UTERUS REMOVED BY HYSTERECTOMY.

I thought it would be interesting, owing to an obstacle. The operation of vaginal hysterectomy where there is no obstacle is so easy and so well defined that there is very little to be said about it, but every once in a while a case occurs where there is difficulty in making the diagnosis and performing an operation. This specimen was from a lady sent to me by Dr. Sanford, of Everett. The disease was noticed last July. A specimen was sent to Dr. Whitney who pronounced it cancer. I saw her on Saturday, and operated last Monday. On examination, the disease seemed limited. The uterus could be freely moved up and pressed down without ether, but when it came to operating the growth would not come down, and I at first thought it might be owing to impaction of the broad ligaments; but the ligaments seemed reasonably free from disease. The contour of the uterus could not be accurately made out. On opening the cul-de-sac of Douglas, the uterus would not come down. When I had severed so much of the broad ligaments that the uterus should have come down, it could not be retroverted. Reaching the finger far up I found quite a mass. I made out that the mass was on one side of the uterus, and by tying the ligament on the other side I was able to slip it out sideways, and found this fibroid tumor in the fundus, that being the principal point of interest in regard to the case.

In regard to the performance of the operation I feel a little more free to speak in this section than in a general section. I have been taking a good deal of interest in the question whether to operate with clamps or with the ligature. As you know the operation with

clamps is common in France, and in this country I think it has made its way, so that it is generally used. In Germany, the ligature is used almost altogether. After seeing Olhausen operate year before last with catgut, that seemed so pretty as compared with the clamp operation that I was incited to try it. It has certain advantages and certain disadvantages. In the first place, I am persuaded catgut will do whatever it is necessary for a ligature to do. It has the advantage that the clamps are not there to irritate the patient, that there is less danger of injuring the viscera by pressure, and there is not the trouble in removing the clamps the second day; it also avoids the disadvantage that when the clamps stay in the vagina two days the plating comes off, so that it is expensive and troublesome keeping them clean and having them replated. It is easier and quicker to do the operation with clamps than with ligatures, especially for beginners, and it has seemed to me that the clamps could be put on farther from the uterus than the ligature. Those two points are all that there is to offset the advantages in finish and technique and easy convalescence in the operation with ligature.

DR. F. L. BURT: As Dr. Cushing has shown this specimen, I think it might be interesting to relate a case I have seen within a few days, of hysterectomy which was performed four years ago. A year ago I saw a lady with Dr. Hardy, who was taking care of her. At that time she was very fleshy, and apparently in perfect health. She gave a history of having had uterine cancer three years before, and that Professor Byford, of Chicago, had removed it. At this time she gave a history of pain just above the left groin. I made an examination to try to find out whether there was any cancer of the pelvis or not. I found that the uterus was gone and there was no evidence, under ether, of any development of cancer. Nothing was done. About last spring she began to suffer so much that she had to have medical attention, and has been treated from that time on. There has not been any treatment of any kind that has been of any service except to relieve pain. She has complained of pain so severe that about a week or ten days ago she was taking very large doses of morphia. The pain was in the neighborhood of the kidneys. There was no complaint of pain or tenderness at any other point. She wasted away so that a few days ago, the time she died, last Sunday, there was not much of anything of the body except a bloated condition. The limbs were quite a good deal swollen. At the autopsy, there was found a liver about one-third larger than normal, and at least two thirds was fatty, degenerated in masses, some of them as large as the fist, and from that down to little ones. She had not complained of the liver. The digestion and appetite had been good all the time. The left kidney was nothing but a sac, no kidney at all. The right kidney was about one-half gone. The bladder was small and about two-thirds filled with a cauliflower-looking material which looked like cancer. I know only just from the microscopic appearance. There has not been any examination made, and the only symptom that she has had that would account for any trouble about the kidneys or bladder has been frequent hemorrhages, and she had felt better after those hemorrhages. There was no tenderness over the bladder, but the bladder was two-thirds filled with this mass, and everything in the pelvis was matted together so that it was one solid mass,

and that woman has been passing urine naturally, except at times bloody, and no symptom whatever except pain in the kidneys. The peculiarity of the case was the few symptoms and the extensive disease of different organs, which presented no symptoms at all, and the fact that all this had not presented itself until after about three years following this vaginal hysterectomy by Professor Byford.

DR. CUSHING: About a month ago in the *Archives of Gynecology*, a New York publication, there was a severe article by Dr. Evans, which was given the place of the leading article, condemning the operation. Tait also disapproves the operation in toto, on the ground that anything that recurs is sure to be cancer, and anything that does not recur is not cancer. This article by Evans, would not amount to anything except that he shines in the reflected light of Tait, who seems proud of his ignorance of microscopic diagnosis. I should be glad to know if that opinion is held to any considerable extent, and if so, why? It seems to me if a woman can be taken off her bed and have from six months to two or three years of health, that is a positive gain and legitimate surgery. Tait is quoted again and again. At the time of the National Congress in Washington, Reeves Jackson made a great onslaught on the operation, and there have been grumblings ever since, but the consensus of enlightened surgical opinion is entirely in favor of the operation.

MASSACHUSETTS MEDICAL SOCIETY.

COUNCILLORS' MEETING.

A STATED meeting of the Councillors was held at the Medical Library, Boston, on Wednesday, February 3, 1892.

The meeting was called to order by the President, DR. A. H. JOHNSON, of Salem, at 11 A. M.

Sixty-nine Councillors were present.

Delegates were appointed to other State Medical Societies as follows:

Maine. — Drs. G. W. Snow, of Newburyport; C. C. Tower, of South Weymouth.

New Hampshire. — Drs. F. W. Graves, of Woburn; H. K. Foster, of Peabody.

Rhode Island. — Drs. D. M. Edgerly, of Cambridge; C. C. Odlin, of Melrose.

Connecticut. — Drs. A. H. Johnson, of Salem; J. C. Warren, of Boston; H. R. Steidman, of Roslindale.

New Jersey. — Drs. F. A. Rogers, of Brewster; J. A. Gage, of Lowell.

In accordance with the report of the Committee on Membership and Finance, three Fellows were placed on the retired list, one Fellow was dropped for non-payment of dues, one was restored to his membership in the Society, and thirty-three Fellows were reported to have surrendered their membership, under By-law VI, by removal from the State.

The committee further reported that, in accordance with a vote at the previous meeting, they had received the funds and papers of the Society from the retiring Treasurer (Dr. Draper), had audited the same, and found them entirely correct, and had transferred them to the Treasurer-elect (Dr. Forster), receiving from the latter the usual bond and sureties.

In accordance with the recommendation of the committee, Dr. George Phokas, of Athens, Secretary of

the Royal Medical Society of Greece, was elected to honorary membership.

Several petitions for restoration to membership were, in accordance with custom, referred to Committees from the respective District Societies in which the petitioners reside.

A petition was presented from the Massachusetts Society for the Prevention of Cruelty to Animals, requesting the action of the Massachusetts Medical Society as to whether in its judgment *any law, and if so, what law*, should be enacted by our legislature to restrict or limit the practice of vivisection by physicians, medical or other students or pupils, in *medical or other colleges or schools*.

The petition was referred to Drs. H. P. Bowditch, of Boston; F. A. Howe, of Newburyport; and J. F. A. Adams, of Pittsfield, as a committee to report at a future meeting.

DR. FITZ called attention to the fact that efforts are being made to erect a monument in Washington, D. C., to Dr. Benjamin Rush, and spoke in favor of the movement.

It was voted that a committee of three be appointed by the President to call the attention of the medical profession and its friends in Massachusetts to the efforts now being made to erect a monument in Washington to Dr. Benjamin Rush. This committee is empowered to receive and forward all subscriptions for the above purpose.

The following were appointed to constitute the committee: Drs. J. C. Warren and John Homans, of Boston; T. H. Gage, of Worcester.

DR. FORSTER, by request, presented the following, which was voted: That a committee of five be appointed to report at a future meeting what changes, if any, may be necessary or expedient to secure a uniform examination of candidates for Fellowship.

The committee was appointed as follows: Drs. T. M. Durrell, of Middlesex South District; G. C. McClean, of Hampden; J. H. McCollom and H. L. Burrell, of Suffolk; C. F. Withington, of Norfolk.

The PRESIDENT presented obituary notices of Drs. Henry I. Bowditch and Claudius M. Jones.

THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

MEETING, December 12, 1891.

DR. R. A. KINGMAN reported, by invitation,

A CASE OF LAPAROTOMY FOR OVARIAN DISEASE.¹

DR. J. W. ELIOT had found in a number of cases a region of dulness in the abdomen in front with tympany below all around. This is due simply to adhesions binding the intestines down.

DR. F. B. HARRINGTON said that ascites with a pelvic mass always makes one suspicious of papilloma.

DR. J. G. BLAKE was present at the operation, and was struck with the completeness with which the disease was removed, although at first sight this seemed impossible. In one case of his own, as the pelvis was found so full of the mass, it was deemed best to do nothing. Life was prolonged by aspiration, from time to time. The prognosis is unfavorable, no matter what you may do.

¹ See page 140 of the Journal.

DR. C. M. GREEN reported a case of

PAPILLOMA OF THE OVARY AND FALLOPIAN TUBES.²

DR. GEO. HAVEN said this case illustrated how difficult it was to diagnose the nature of any intrapelvic growth, without opening the abdomen. Dr. Green felt quite sure that we had to do with an ovary and tube, and the idea of a papilloma did not occur to me. What the nature of the mass was which appeared on the twelfth day must remain a mystery, and as far as the patient is concerned, is proved to be of no moment.

Dr. Mallory said that when the cellular elements of the growth were not very marked the danger of return was much less, and this was true of the specimen from this patient.

DR. ELIOT said that where the papilloma is removed in an unruptured cyst there may be no recurrence, whereas if the peritoneum is involved there is scarcely any hope. Scraping the peritoneum is of no use. Of course, if but a small portion were involved this should be cut out, with the hope of arresting the disease.

DR. HARRINGTON would remove a large tumor with a pedicle, simply for the purpose of getting rid of the mass, but would not subject the patient to a long operation.

Dr. Harrington showed a specimen of

GLANDULAR CYSTOMA,

and related the case. Two months ago the patient had acute pleurisy of the right side with large effusion. This subsided in a few days under the use of cathartics. Then ascites rapidly developed, and tumors feeling like fibroids were found.

Three weeks ago she was tapped and twenty pounds of fluid drawn off, which was examined by Dr. Whitney, who said it suggested papilloma. Yesterday he performed laparotomy, as the ascites had come on again in a few days. A tumor of the left ovary was removed. There was no evidence of disease of the peritoneum, although that was much inflamed. The tumor, which was soft and friable, resembling brain substance, nearly filled a basin. The fluid in the chest was apparently only coincidence.

DR. EDWARD REYNOLDS reported

CASES OF LABOR COMPLICATED BY PROLAPSED OVARIAN TUMORS.³

Owing to the lateness of the hour the discussion was postponed till the next meeting.

Recent Literature.

Addresses, Papers and Discussions in the Section of State Medicine at the Forty-second Meeting of the American Medical Association. Chicago. 1891.

These eleven papers constitute a valuable addition to the literature of State Medicine. Dr. N. S. Davis, the chairman, contributes a paper on the "Relation of Meteorological Conditions to the Origin and Prevalence of Acute Diseases." Dr. Geo. W. Jenkins furnishes a paper on "Hygiene in the Rural Districts." Dr. A. N. Bell on the "Beneficence of Disease, the General Purport of which is not Medical but Theological." Dr. H. O. Marey contributes a concise, pointed paper

on "The Coroner System in the United States," in which special comment is made upon the operation of the Medical Examiner System of Massachusetts. Dr. Jos. R. Smith, U. S. A., gives many valuable "Statistics of the Sickness and Mortality in the United States Army."

DR. L. F. FLICK takes very strong ground in his paper on "The Duty of the Government in the Prevention of Tuberculosis," in favor of preventing the disease by the action of sanitary authorities. The writer very plainly believes that it is not only within the power, but that it is the duty of such authorities to take all possible means for its prevention.

DR. STERNBERG's paper on "The Disinfection of Excreta" brings the subject down to date, and is mainly a commentary on the Report of the American Public Health Association of 1884. The substances recommended are chloride of lime, carbolic acid, creolin and quick lime. With reference to the latter he says, "We are disposed to give recently burned quick lime the first place for the disinfection of excreta in privy vaults, or on the surface of the ground." Under favorable circumstances "boiling water in the proportion of three or four parts to one part of the material to be disinfected, may be safely recommended." He emphasizes the fact very strongly that "there can be no disinfection in the absence of infectious material." DR. P. H. BRYCE contributes a paper entitled "The Sanitary and Unsanitary Relations of Underground Waters." DR. CHANCELLOR's paper on "Simple Methods of Sewage Disposal" is devoted mainly to the disposal of household sewages, and special prominence is given to a device of the author's invention in which the solids are separated by means of an iron precipitating tank.

DR. R. H. REED contributes some excellent original "Investigation on the Heating and Ventilation of School Buildings," somewhat after the method employed by Professor RIETSCHEL, of Berlin, in 1885. The observations were made in four cities of Ohio, and in thirty-nine schools, and had reference to the number of pupils present, the cubic air-space, the temperature, humidity, barometric pressure, fresh air supply, amount of carbon dioxide at different heights in the rooms and other important points. Emphasis is given to the well-established fact that the carbon dioxide in occupied apartments is uniformly diffused through the air at different heights and is not massed at the bottom of the room.

DR. D. F. LINCOLN gives a few brief principles to be observed in the construction of school buildings.

The Chinese, their Present and Future: Medical, Political and Social. By ROBERT COLTMAN, JR., M.D., Surgeon in charge of the Presbyterian Hospital and Dispensary at Jeng Chow Fu, etc. Illustrated. Philadelphia and London: F. A. Davis. 1891.

The author of this book spent several years in northern China as a medical missionary physician on the staff of the American Presbyterian Board of Foreign Missions. He had excellent opportunities for observation of the people among whom he practised his profession. His statements apply to the inhabitants of northern China; the manners, customs, characteristics and even the language of southern China differ in many respects from those of the north. DR. Colman has written a very readable book, illustrated with reproductions of photographs taken by himself.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, FEBRUARY 11, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTIONS: \$5.00 per year, in advance, postage paid, for the United States, Canada, and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
 283 WASHINGTON STREET, BOSTON, MASS.

ANNUAL REPORTS OF THE PRESIDENT AND TREASURER OF HARVARD COLLEGE, 1890-91.

FROM the report of the Dean of the Harvard Medical School, we learn that the whole number of students in attendance in that department of the University during the year was 353, as compared with 304 in the preceding year. Of these fifty per cent. had literary or scientific degrees. There were 65 applicants for the degree of Doctor of Medicine in the three-years' course, of whom 16 were rejected. There were applicants for the same degree in the four-years' course, of whom none were rejected; 10 of these students received the degree *cum laude*, and 11 received the degree of Master of Arts together with that of Doctor of Medicine. The fourth class was composed of 26 students, as compared with 23 last year.

The difficulties, which for the last thirteen years have attended the plan of offering a required three-years' and an optional four-years' course of instruction, have been removed by the vote of the Faculty passed last May to establish a single four-years' course to go into effect in September, 1892.

The Faculty has not lost sight of the possible diminution of the number of students consequent upon this increase in the requirements for the degree, but it feels perfect confidence that the community which has enabled it to carry out its previous educational reforms, will respond favorably to any appeal it may have to make again for the realization of unselfish purposes which must in turn be of direct benefit to the community itself. The Faculty has no apprehension that loss of direct income will be allowed to interfere with the school's work.

The opening of the Sears' Laboratory building has not only directly benefited the departments of pathology and bacteriology, but indirectly those of anatomy, histology and embryology, by placing improved accommodations at the disposal of the teachers of these subjects.

The connection between the Medical School and the other departments of the university has been made

closer during the past year by the adoption of a recommendation that certain laboratory courses, distinct from the regular instruction given to medical students, be recognized as suitable courses for students in the Graduate School. By a recent vote these courses have also been thrown open to candidates for the degree of Bachelor of Arts, thus enabling undergraduates intending to enter the medical profession to accomplish the very desirable object of shortening their period of academic training.

The Dean refers with much satisfaction to an important addition to the school's means of encouraging original research in medicine made by the establishment, through the generosity of Wm. S. Bullard, Esq., of three fellowships of \$5,000 each, to be designated as the George Cheyne Shattuck, the John Ware, and the Charles Eliot Ware Memorial Fellowships. The income of these fellowships may be paid to any "student or member of the medical profession who shall be selected by the Faculty of the Medical School to make such original investigations in medical science as in their opinion will be most useful to the profession and the community."

A vivifying influence upon the prosperity of the Medical School is anticipated from the recent formation of the Harvard Medical School Association, which already has upon its rolls the names of 835 members. From these alumni gratifying proofs are being constantly received of attachment to, and enthusiasm for, the university and the school.

Much special work, in addition to its regular instruction, has been done in the past year in the departments of anatomy, histology and embryology, physiology, chemistry, pathology and bacteriology.

The amount of instruction in the clinical department, which, after all, must be regarded as the most important department of a medical school, has been constantly increased.

The Dean of the Dental School reports the number of students matriculating as 44. The instruction in anatomy, physiology and chemistry is given at the Medical School, in addition to which some of the teachers at the Medical School have given lectures. Some new courses of instruction in dentistry have been added. The Faculty of the school and the alumni association are much impressed with the urgent necessity of better accommodations for the school. Its endowment has been increased by a gift of \$7,000 from an anonymous benefactor who had already given \$6,000. The school is now out of debt and has an endowment of \$15,205, beside a favorable balance of \$3,817; but the present situation is obscure and inconvenient, and the building is not well adapted to its purposes. The high standard of the school necessarily limits the numbers of the students, so that it is practically carried on by the public spirit of its instructors. They have done much, and hope to do still more towards putting the school on a firmer foundation in a suitable building of its own.

The Veterinary School has an increase of fifty per

cent. in the number of applicants for admission. A new and important instructorship in bovine pathology has been established which will be filled by Dr. F. H. Osgood, of Springfield, who will also assume other and still more important relations to the hospital. Mr. W. O. Underwood will give a course of practical talks upon the law of sales and warranty, which will embrace a general discussion of rules of evidence, with suggestions on expert testimony and the conduct of witnesses in court. The school is not self-supporting, but has been carried along by the hospital. It is very essential that either the school should be endowed, or that the hospital should be provided with larger quarters, and thus given a greater earning capacity. The two ought not to be separated.

THE QUARANTINING OF INFLUENZA.

THE attempt to deal with influenza as a disease dangerous to the public health is made the subject of comment in the *Local Government Chronicle* of January 16, 1892, as follows:

Dr. Parsons, who reported on the disease to the Local Government Board in July last, came to the conclusion that it was an infectious disorder, communicable in the ordinary personal relations of individuals one with another; and Dr. Buchanan recorded his opinion that henceforth there could be no doubt about this fact. Probably the Walmar and Ashford Local Boards rely on these opinions as justifying the notices which they have issued of their intention to proceed against persons for penalties who expose themselves in public while suffering from the disease. It is not, however, very likely that any very substantial results will follow prosecutions of this character. In commenting on the report of Dr. Parsons, Dr. Buchanan was careful to point out that early isolation precaution, which is so efficacious in preventing the spread of some infectious diseases, cannot well be applied to persons suspected of influenza among the bread-winners of a community; and he also drew attention to the brief incubation period of the disease, which enables it to give rise to some thousand attacks in the time that small-pox or typhus take to produce ten. He further stated that a better understanding of the natural history of the disease was a necessary preliminary to the discovery of better means for its prevention. In other words, the public are at present unable to protect themselves in any way against the malady; and, if this is the case, it is hardly worth while proceeding for penalties against the unfortunates, who, while suffering from the disease, venture to show themselves abroad. If the epidemic lasts a year or two longer, the chances of learning more about it will be multiplied. But considering the time during which diphtheria has been prevalent in this country, and the little that is yet known positively about it, it is impossible to feel sanguine that a solution of the whole mystery will be very soon arrived at. In the mean-

while, medical officers of health will do well to study Dr. Parsons's report, and to make the most careful records of their experience of the behavior of the disease.

The difficulties in the way of isolation are many and immediately suggest themselves; moreover, it still seems to us that transmission alone from person to person fails to explain many trustworthy observations and unquestioned features.

VACCINATION STATISTICS.

DR. JOSEF KÖRÖSI, director of the Buda-Pesth municipal statistical bureau, has lately written a pamphlet¹ in continuation of the "Kritik der Vaccinationsstatistik," which the author presented to the International Congress of Medicine, at Washington in 1887, the present paper having been presented to the tenth session of the same congress at Berlin, in 1890. It includes the statistics of 1886, presented in the earlier paper, to which are added the statistics of 1887 and 1888, as observed in nineteen hospitals in Buda-Pesth and in other provinces of Hungary.

The material of the statistics consists of observations made upon the patients admitted and treated in these hospitals for three years, the deaths which occurred in them, and the deaths which occurred throughout the provinces. These observations had reference to the condition of each person with reference to vaccination, making in all nearly 112,000 observations.

As a result of these observations the author concludes, that, if any slight increase of mortality can be charged to vaccination, with reference to certain specified diseases, there should also be placed to its credit a saving of life, at least three-hundred fold as great.

Körösi stands easily at the head of living statistical authorities upon vaccination, hence his conclusions are entitled to great respect. He attaches to vaccination a greater preventive power than to any other known means or appliance in the whole field of medicines.

MEDICAL NOTES.

DEATHS IN CHICAGO FROM TYPHOID FEVER.—The number of deaths from typhoid fever in Chicago, from January 2d to 30th, 1892, was 285. This is the highest since last May, when it was 408. July, 1891, comes next, with 200.

MORTALITY OF NEW YORK STATE IN 1891.—The summary of the State Board of Health of New York, shows that during the year there were 123,878 deaths. Of these, 20,697 were from acute respiratory disease; 13,445, from consumption. There were only four deaths from small-pox. Epidemic influenza is estimated as having caused 8,000 deaths during its prevalence in March, April and May, and 2,000 on its reappearance in December. This is double the number

¹ Neue Beiträge zur Frage des Impfschutzes, Pottkamer & Mühlbrecht, Berlin, 1891, pp. 71.

supposed to have been caused by the epidemic in 1890. It was distributed uniformly through all the districts.

THE CARTWRIGHT LECTURES of the Alumni Association of the College of Physicians and Surgeons of New York for 1892 will be delivered at the New York Academy of Medicine, February 12th, 19th and 26th, by Prof. Henry F. Osborn, of Columbia College. Subject: Present Problems in Evolution and Heredity. (1) The Contemporary Evolution of Man. (2) The Difficulties in the Heredity Theory. (3) Recent Studies upon the Germ-cells. The profession is invited to be present.

THE INSTITUTE OF HYGIENE OF THE UNIVERSITY OF PENNSYLVANIA, will be formally opened on February 22d. The following programme of ceremonies to be held in the Library of the University has been issued, to begin at 3.30 P. M.: Prayer, by the Rev. Dr. George Dana Boardman. Presentation of the new building to the Provost and Trustees, by Dr. S. Weir Mitchell, Chairman of the Committee on Hygiene. Acceptance on behalf of the Provost and Trustees, Provost William Pepper. Address, Dr. Benjamin Lee, Secretary of the State Board of Health. Address, Dr. John S. Billings, Director of the Institute. Address, Dr. H. P. Walcott, President of the Massachusetts State Board of Health. Inspection of the new Institute of Hygiene.

NOSE-CUTTING.—The Judges of the High Court of Bombay, says the *Medical Press*, have determined to make an effort to put a stop to the perpetration of the crime of nose-cutting, a form of crime very commonly practised among the native population of India, solely as a punishment for supposed or real marital offences. In the Indore Hospital, several wives were exhibited who had lately been operated upon for the restoration of their noses by the well-known flap-operation. The greater part of these women are young and pretty, and jealousy alone was the motive for this form of cruelty.

SUFFOCATION OF INFANTS IN BED.—The last annual report of the Registrar-General, in England, shows that during the year 1890, 1,500 children were killed by being suffocated by their mothers. Most of the cases were, undoubtedly, accidental; the mothers rolling onto the children during sleep. It was found that the proportion of deaths of infants from overlying is more than twice as high on Saturday night as on any other night in the week. The Registrar-General explains this fact as due to the greater amount of intoxication on Saturday than on any other day, as it is a general pay-day. Sunday and Monday nights yield the next largest proportions of such deaths.

THE PROPER WAY TO PREPARE TEA.—The *British Medical Journal* in commenting on the death of a boy who died from drinking hot tea without milk, says that the tea had been left in the oven for some time, so that it had become a strong decoction of tannin. In being drunk without milk, the tannin was not brought into a relatively harmless albuminous tannate. It is

on account of this method of making tea that it is so injurious to the digestion. Neither the Chinese nor the Japanese, who know how to make tea, use milk with it; but with them the hot water is poured on and off the leaves at table, and it is drunk as soon as it becomes a pale straw color. No people in the world drink so much tea as the Japanese, yet in Japan it is never injurious to the digestion, as by their method of preparation, the tannin is not extracted from the leaves.

NICE AS A HEALTH RESORT.—The European edition of the *New York Herald* for January 16th contains a supplement describing the climatic and sanitary condition of Nice, founded on the investigation of Dr. E. C. Wendt, in behalf of the *New York Medical Record*. The health authorities of the town have apparently become convinced of the importance of pure drinking-water and good drainage, and have already undertaken to correct the previous bad condition of both. The conditions of the drains themselves were not in as bad a condition as the connection between the drains and the hotels.

NEW ENGLAND.

THE DEATH-RATE IN BOSTON.—The death-rate has returned to normal limits. There were 185 deaths reported last week, as against 168 the corresponding week last year. The death-rate per thousand is 20.9. Fifteen deaths were reported as due to influenza, from consumption 23, pneumonia 24, bronchitis 15. The number of persons over sixty years of age was 35.

APPROPRIATION FOR THE CARNEY HOSPITAL.—The Boston Common Council has voted to request the Mayor to petition the legislature for the passage of the act granting authority to the City of Boston to appropriate a sum of \$5,000 annually, for the maintenance of the Carney Hospital.

GIFT TO THE LOWELL HOSPITAL.—Ex-Senator F. W. Howe has given \$5,000 to the Lowell General Hospital, to establish a free bed.

TO ADVANCE MEDICAL SCIENCE.—A bill has been introduced in the Massachusetts House of Representatives, calling for the appointment by the Governor of a commission of five citizens, who shall be known as the Commissioners of Medical Science. It shall be their duty to convene at the call of the Governor, and to give hearing to any matter brought before them which has to do with any principle or system of principles looking to the practical advancement of medical science. The Governor and council are authorized by the bill to expend \$5,000 for rewards to further the impetus of genius and research in the development of medical science.

THE ANNUAL REPORT OF THE MASSACHUSETTS STATE BOARD OF LUNACY AND CHARITY.—According to the annual report of this Board, during six months from April 1st to October 1st, there were 40,016 aliens landed in the port of Boston. Of these, 24,437 came from transatlantic ports and 15,579 from Canada. After the 1st of April the new emigration

law came into effect. Of the aliens from transatlantic ports, 364 were detained for further examination; of these, 83 were permitted to land; 156 were required to give bonds, and 119 were returned to the countries from which they came. In connection with public farms, the report says: "It is evident that very much more could be accomplished in the way of preventing frightful abuses connected with these places and the consequent destruction of infant's lives, if the matter of licensing and regulating all places in which infants are taken to board as a business were placed in the hands of a State Board."

NEW YORK.

REPORTERS AT EXECUTIONS BY ELECTRICITY.—Both houses of the Legislature have passed, and Governor Flower has signed, the bill allowing the presence of reporters at executions. The selecting and appointing power is vested in the warden of the prison where the execution takes place.

MEDICAL SOCIETY OF STATE OF NEW YORK.—On February 4th the Medical Society of the State of New York, in session at Albany, elected the following officers for the ensuing year: President, Dr. Louis S. Pitcher, of Brooklyn; Vice-president, Dr. H. L. Eisner, of Syracuse; Secretary, Dr. F. C. Curtis, of Albany; Treasurer, Dr. C. H. Porter, of Albany. Drs. Eugene Beach, of Gloversville, E. P. Creveling, of Auburn, B. F. Sherman, of Ogdensburg, and A. W. Suiter, of Herkimer, were recommended for State Medical Examiners.

THE HARRIS MURDER CASE, terminated last week, has excited extraordinary interest among the medical profession on account of the expert evidence brought forward and the questions of medical jurisprudence involved. The justice of the verdict rendered, though the latter was founded purely on circumstantial evidence, seems to be generally acknowledged; though it is regarded as peculiarly unfortunate that the autopsy was not made until fifty-three days after the death of the victim. There is one point in which the defendant Harris clearly overreached himself, and that was in preserving two of the capsules which he prescribed for his wife, in order to show that they contained only an ordinary dose of morphia; for had none of these capsules come into the possession of the prosecution it could not have been proved beyond question that the druggist had not made a mistake in putting up the prescription.

A UNIQUE CASE was presented by Prof. E. G. Janeway at his clinic at Bellevue, on February 1st. The patient, who is the proprietor of a small hotel on the river front, breathes at the rate of 152 times a minute, and chronic inflammation of the trachea has resulted from this rapid respiration. The shortness of breath has incapacitated him for hard work, but otherwise he appears to be in fairly good health, a careful examination of the heart, lungs and other organs revealing the presence of no disease. The

extraordinary rapidity of respiration is believed to be due to a lesion of the medulla oblongata resulting from an injury which he received more than two years ago. The man states that in the autumn of 1889, while serving on the Boston police force, he was thrown from the platform of an electric car, striking the pavement with his shoulders and the back of his head. In consequence of this fall he remained in an unconscious state for ten days, and when he recovered his consciousness he found that he was breathing, as he expressed it, "like a steam engine at high pressure." The rapid breathing has continued ever since, and he furthermore states that once or twice a month he suddenly becomes unconscious, and remains in this condition for several hours. This man presented himself at one of the hospitals in Boston more than a year ago, and has been under the observation of several physicians in Boston.

Miscellany.

THE BACILLUS OF INFLUENZA.

CANON,¹ in a further communication on the influenza bacillus found by him in the blood, says, that as the number of bacilli in a drop of blood is so small that they are hard to find, he has succeeded in cultivating them in the blood-drop itself. Separate drops of blood are put into an incubator and kept at a temperature of 37° C. In twenty-four hours the colonies have already begun to develop, and in forty-eight hours they can be easily found. From these colonies other colonies may be started upon different media. The pure cultures thus obtained have the same appearance as those already described by Kitasato.

TYPHOID FEVER IN CHICAGO.

The Health Officer of Chicago states, through the daily press, that an investigation made by him shows that only three deaths out of every fifteen reported at his office as being caused by typhoid fever is correct. This is about the worst reflection on the diagnostic ability of more than two thousand physicians that has ever come under our observation; but it parallels right along with the same official's statement that the lake water at the crib is free from contamination, as shown by chemical analyses made from time to time in his office.

Evidently the Illinois State Board of Health are quite skeptical in their belief of these official utterances, as indicated by their appointment of Dr. John H. Rauch as Sanitary Expert and Counsellor, with directions to at once examine and report upon the unsanitary conditions which are so productive of sickness, and the high rate of mortality from enteric disease in Chicago. . . .

It would be a right good thing for any one of the Chicago Medical Societies to appoint a good large committee of its best-known members to examine into and report upon the existing conditions in the Chicago Health Office. Official reports are either very valu-

¹ Deutsche med. Woch., January 21st.

able, because of their truthfulness, or misleading to the extent of actual criminality when fictitious. — *Journal of American Medical Association*, February 6, 1892.

NEW YORK AMBULANCE SURGEONS.

ADVANTAGE has been taken of this occurrence¹ in regard to which the autopsy shows the ambulance surgeon was blameless to abuse not only the ambulance surgeons of the hospital concerned in it, but the ambulance surgeons of New York as a class; they have been held up to the scorn and reprobation of the community. It is high time that a word should be spoken, and loudly spoken, in behalf of the young men in our hospitals. A more meritorious, intelligent, hard-working, conscientious set of young men cannot be found. They work hard and long to obtain their positions, which they do by giving proof of superior intelligence and acquirements, and they work hard and long while they hold them, in order the better to fit themselves for the practice of their profession. In a word, they are the flower of the younger men, and in a few years they will stand fully ahead of the best of the older ones. If they cannot do the work well, it cannot be done well. But, notwithstanding all that has been said, notwithstanding their liability to error, and notwithstanding their inability to see what is invisible, and to touch what is intangible—an inability which they share with the rest of mankind—their work is well done. The superintendent of one of our largest hospitals, when recently asked by a reporter if the present system of ambulance service was satisfactory, replied that it was, and "eminently so." And in this opinion of an impartial, and necessarily even an exacting, superior, we are confident that all who have personal knowledge of the matter will heartily concur. — *New York Medical Journal*, February 6th.

UNIQUE THEORIES OF THE MECHANISM OF LABOR.

THE *Maryland Medical Journal* criticises editorially the freedom of the medical press, when it receives without comment, articles containing recommendations of dangerous appliances, founded on grotesque theories. The case in point is an "atmospheric tractor" and a "uterine safety tube," the latter, essentially a soft rubber catheter to be introduced into the uterus during labor. The theory of the inventor is that "the power which expels the fetus is the force of super-heated air which is collected in the womb behind the child's body and expands with a rise of temperature in the womb during labor."

This sounds so much like an article which appeared in a medical monthly a few months ago, introducing an "atmospheric tractor," that we are inclined to believe that the author is the same; but in the mean time he has apparently changed his theory of labor, for in the article in question he says:

"When the uterus contracts round the body of the child, it expels all or nearly all the air from the uterine cavity, just as, when the hand firmly grasps a ball, the air is squeezed out from between it and the palm and fingers. The abdominal muscles then contract, forcing

the fundus of the uterus down and pushing the child's body and head into the pelvic cavity. While this is occurring, there is a partial vacuum in the upper part of the uterus or that portion of it which is firmly contracted around the child. When the abdominal muscles relax, the pressure of the external air, and the expansive pressure of the air in the vagina are exerted against the head and shoulders of the child, and force it back until sufficient air enters the uterus to overcome and break up the vacuum and elevate the fundus. . . . That the retrocession of the head is due to atmospheric pressure almost altogether and only in a small degree to muscular resistance or pelvic rigidity, must be obvious to those who have felt the head stop and recede before it had reached the pelvic floor and while it was still suspended in space, a half an inch or more above the muscles."

DISINFECTION OF THE HANDS.

DR. H. A. KELLY,² after giving the details of a large number of experiments made by himself and his associates, gives the following conclusions as to the best method of disinfecting the hands:

Scrubbing the hands with especial attention to the nails, — not more than one millimetre in length,—for ten minutes in water, frequently changed, at about 104° F. Immersion of the hands in a solution of permanganate of potassium, made by adding an excess of the salt to boiling distilled water, until every part of the hands and lower forearms is stained a deep mahogany red or almost black color. They are then transferred at once to a saturated solution of oxalic acid until completely decolorized and of a healthy pink color. Washing off the oxalic acid in warm sterilized water.

By this simple process the hands are rendered more nearly absolutely aseptic than by any other known means.

The author has found that it is impossible to get rid of staphylococci by scrubbing the hands and nails with ten to twenty-five minutes with a sterilized brush, soap, and water, temperature 104° F. The bichloride of mercury solutions as used, up to 1 : 500, are not germicidal, as supposed. Previous erroneous conclusions as to the efficiency of the bichloride are shown to be due to an inhibiting action which may persist at least twenty-four hours after the last use of the drug. Hydrogen peroxide and lysol (four per cent.) were tested and found wanting.

In the present state of our bacteriological knowledge as to the causes of inflammation and suppuration, we are bound to use every means in our power to avoid sowing any unnecessary germs in our wounds. Soap and water are, Dr. Kelly believes, the best disinfectants, if we use but one, for they remove all germs which will come away easily. The bichloride of mercury, although dangerous on wounds on account of its property of coagulating and causing necrosis of albuminous tissues, has the valuable property of inhibiting those germs with which it comes into contact. Permanganate of potassium and oxalic acid are harmless to the hands and are germicidal. Soap and water plus the permanganate of potassium and oxalic acid are the only true germicides, and therefore the best disinfectants we possess to-day.

RESOLUTIONS OF THE GALEN MEDICAL CLUB, ON THE DEATH OF DR. C. M. JONES.

WHEREAS, we, the members of the Galen Medical Club, have learned with deep regret and sorrow that our friend and fellow-member Claudio Marcellus Jones has fallen in the battle of life, we desire to express our appreciation of his worth as a man, his skill as a physician and his unflinching devotion to his duties, in the performance of which he received the wound which, emphasized by too arduous labor in his chosen field, eventually caused his death.

Prodigal of work, frugal of words, his ripened scholarship, evidenced by his degree from Harvard, "summa cum laude," was ever at the service of his friends, as were to the poor and suffering his services as a physician regardless of the question of pecuniary reward.

Though he died just as he was about to enjoy the fruits of long years of work, those who knew him best know also that the satisfaction of duty well performed was to him the source of the greatest happiness. We shall cherish his memory as that of a valued friend and a man who was distinctly the type of what the true physician should be; and he will ever remain an exemplar whose career should be emulated by us and by all those who adopt the profession of medicine.

G. M. GARLAND, M.D., Secretary.

THERAPEUTIC NOTES.

PREVENTION OF COCAINE POISONING. — Smith¹ recommends that patients be prepared by giving them a drop of a one per cent. alcoholic solution of trinitrine a minute before administering the cocaine, repeating the dose at intervals if the pulse be not affected and no pain or fulness in the temporal region be felt. The trinitrine acts almost as rapidly and continues to affect the vaso-dilators for upwards of half an hour longer than nitrite of amyl.

PIPERAZIN. — This substance in aqueous solution dissolves twelve times as much uric acid as is dissolved by the same quantity of carbonate of lithium. There is formed a neutral urate of piperazin, which is seven times as soluble as urate of lithium. Piperazin itself and also the hydrochloride are easily soluble in water. The dose is from fifteen to forty-five grains a day. It may be prescribed as follows:²

R. Piperazin gr. xv.

Acid testi. gr. vi.

Syrup Auranst cort. M.

Sig. Take in the course of the day. To be increased gradually.

FATAL POISONING BY CHLORATE OF POTASH. — Dr. M. J. Donahoe reports in the *University Medical Magazine* for January, a case of a man thirty-six years old who took by mistake two tablespoonfuls of chlorate of potash in water. Four or five hours afterwards violent vomiting set in, accompanied by great pain and tenderness in the epigastrum, followed by albuminuria and cardiac weakness, gradually increasing for a week, when the patient died.

CLEANSING OF THE HANDS AFTER THE USE OF CARBOLIC ACID OR CORROSIVE SUBLIMATE. — Carbolic acid is removed from the hands by bathing them for a sufficient time in alcohol and then anointing them with lanolin. After the use of corrosive sublimate solution the hands should be bathed in a solution of common salt 1 to 50, then washed with soap and water, and finally rubbed with lanolin.

¹ British Medical Journal, December 8th.

² Lo. Sperimentale.

Pharmac. Central., No. 28, 1891.

SALOL AS A COATING FOR PILLS. — In consequence of the fact that salol is not dissolved in the stomach, but is only attacked by the pancreatic juice after it reaches the intestine, Dr. Ceppi suggests its use for coating pills intended not to act before they enter the intestines.

R. Salol	gr. xxx.
Tannin	gr. viii.
Ether	3 fl. oz. M.

With this solution the pills are varnished several times, until the protecting layer is sufficiently thick.

COLD IN THE HEAD. — The following powder, to be used as a snuff, is recommended in *Medecine Moderne*.

R. Talei pulv.	3 lbs.
Antipyrin	gr. xxx.
Acidi borici	3 t.
Acidi salicylici	gr. viij.

OLD TINCTURES. — Great care should be taken in administering tinctures which have stood for a long time in small vials. When the bottles happen to be loosely corked the alcohol readily evaporates, leaving the drug in the form of a concentrated tincture, the pharmacopoeial dose of which might produce very serious, if not fatal, results.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 6, 1892, TO FEBRUARY 5, 1892.

The order relating to CAPTAIN AARON H. APPEL, and FIRST-LIEUT. JULIAN M. CABELL, assistant surgeons, U. S. A., is suspended until further orders.

LIEUT-COLONEL JOSEPH F. WRIGHT, surgeon, U. S. A., is relieved from duty at Fort Verde, Arizona, and will report to Fort Leavenworth, Kansas, and will repair to San Francisco, Cal., and assume the duties of acting assistant medical purveyor, taking charge of the medical supply depot at that place, and relieving LIEUT-COLONEL GEORGE M. STEENBERG, surgeon, U. S. A., who, upon being relieved, will proceed to Governor's Island, N. Y., and report in person to the Commanding General Department of the East, for duty as attending surgeon and examiner of recruits in New York City.

FIRST-LIEUT. HENRY D. SNYDER, assistant surgeon, now temporarily serving at Fort Reno, Oklahoma Territory, is assigned to duty at Fort Supply, Indian Territory, where he is now temporarily serving.

FIRST-LIEUT. SAMUEL R. DUNLOP, assistant surgeon, is relieved from duty at Fort Sill, Oklahoma Territory, and assigned to duty at Fort Supply, Indian Territory, where he is now temporarily serving.

MAJOR JOHN BROOKS, surgeon, U. S. A., is granted leave of absence for twenty-eight days.

CAPTAIN AARON H. APPEL, assistant surgeon, U. S. A., granted leave of absence for twenty-three days.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING FEBRUARY 6, 1892.

J. L. NEILSON, surgeon, detached from Training-ship "Portsmouth" and granted two months' leave of absence.

SOCIETY NOTICE.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT.—The Section for Clinical Medicine, Pathology and Hygiene will meet at 19 Boylston Place, on Wednesday, February 17th, at 7.45 o'clock.

Papers: Dr. Gertrude Van Pelt, "Cases of Dyspepsia, with Treatment based upon an Examination of the Gastric Juice."

Dr. A. K. Stone, "Glycosuria caused by a Probable Tumor in the Fourth Ventricle." Dr. P. C. Knapp, "The Provision for Patients with Chronic Diseases in the City of Boston."

ALBERT N. BLODGETT, M.D., Sec'y, 390 Boylston St.
E. G. CUTLER, M.D., Chairman.

RECENT DEATHS.

ROBERT WILLARD, M.D., M.M.S.S., died in Boston, February 6th, aged fifty-three. Dr. Willard was born in Boston, and graduated from Harvard College in the class of 1860. At the outbreak of the war he was a medical student. He entered the navy as assistant surgeon, and served on the monitor Catskill and the flagship Colorado. He received the degree of M.D. from the Harvard Medical School in 1864. Since 1871 he has been ophthalmic surgeon at the Massachusetts Charitable Eye and Ear Infirmary. He was a member of the American Ophthalmological Society, and of the Boston Society for Medical Improvement.

HENRY W. STILLMAN, M.D., of Woonsocket, R. I., died February 5th, aged sixty-seven. He had practised for eleven years in Lime Rock, twenty-seven years in Cumberland and six years in Woonsocket.

SIR MORELL MACKENZIE died in London, February 2d, aged fifty-four. Dr. Mackenzie received his medical education at the London Hospital Medical College, and in Paris and Vienna. In 1852 he founded the Hospital for Diseases of the Throat in Golden Square, London. In the same year he received the Jacksonian Prize from the Royal College of Surgeons for his essay on diseases of the larynx. He soon afterward became assistant physician to the London Hospital, becoming, in due course, full physician, and was appointed lecturer on diseases of the throat, an appointment which he held to the time of his death. He was a corresponding member of the Imperial Royal Society of Physicians of Vienna and of the Medical Society of Prague and an honorary fellow of the American Laryngological Association. In 1887 he was called to attend the crown prince, later the Emperor Frederick III of Germany, who was suffering from disease of the larynx. In controversy which was raised over his diagnosis, treatment and conduct in this case will be remembered. He was knighted by the queen at the request of the emperor. Dr. Mackenzie was a prolific writer and was the author of a large number of publications on laryngological subjects. His chief work was issued in two volumes, under the title of "Diseases of the Throat and Nose."

BOOKS AND PAMPHLETS RECEIVED.

Original Articles.**INTESTINAL ANTISEPSIS.**

BY HAROLD C. ERNST, M.D.,
Assistant Professor of Bacteriology, Harvard University.

This subject is one of the greatest importance to practical medicine. It is true, and it has sometimes been made a subject of reproach to physicians, that the surgical branch of the profession has apparently appreciated more and taken greater advantage of the advances in experimental work of the last few years. The reasons for this are easily to be seen upon even a slight consideration of the subject, and are perhaps no quite so flattering to surgery as has been too easily conceded. Surgical problems of aseptic and antiseptic treatment are, to a very large extent, mechanical in their nature. It is settled that the complications arising in surgical practice in the way of infection and suppuration are due to the activity of the bacteria and their products, and it necessarily follows that the prevention of the appearance of these consequences is a matter of exclusion of the causative agency, — provided the processes themselves do not exist at the time of surgical interference.

So too, with these same processes after they have been once established, — a free exit to the hurtful agencies, — free drainage, in other words, is what is necessary for their cure, and beyond this, even the surgeons have not travelled far in the line of direct cure for such processes.

The matter becomes a very different one as soon as one approaches a medical problem, typhoid fever for instance. In such a case, there is no possibility of adopting the procedure of free drainage or anything else that will secure a sure and speedy exit to the toxic agencies. Prevention, in the case of infectious diseases, stands to-day upon very much the same level as prevention in the case of infectious wound-diseases, except that in the latter, one's attention is confined to the individual case and single patient that is usually under full control, while in the former, the necessary precautions must often be taken before the patient has even come under observation, in fact before he has become a patient at all.

So that even from this point of view the medical problems are more complex than the surgical. This being so, what shall be said of the infinite complexity of those questions of cure, the possibility of which has but just begun to be forced upon our attention by our increasing knowledge of the activity of the micro-organisms in the production of the many forms of disease in which they are now known to be concerned?

In such cases it is not a question of a free exit to agents destructive to vital activity, this to be done once and for good, but of something entirely beyond this, some procedure much more prolonged and much less destructive in itself than an incision of greater or less extent. Before such problems as these can be solved, all the knowledge that has as yet been gained and an enormously greater amount than this, yet to be secured, must be thoroughly appreciated and turned to its proper uses.

In the general study of the action of the micro-organisms in the living body, there are certain facts that have been disclosed that are of general utility in

the consideration of an infectious process, these relating especially to the method of production of their harmful effects. We know that these effects are the result of (1) mechanical obstruction, due to the presence of masses of the organism in the part, and the mechanical destruction of the vital processes in that part; (2) to the appropriation by the invading cells, of the nutritious material necessary for the vitality of the tissue-cells, and the resulting death and necrosis of these latter; (3) to the formation, after various processes of retrograde metamorphosis, of many new chemical compounds in the body, with greater or less toxic effects upon the surrounding vital tissues.

Of these various methods of producing ill-effects, the first is the least common, and the last the most so, and the problem before us is to so study each and every disease that we may know how it is produced, and what are the best means to neutralize or destroy this method of production. This seems like a simple statement, but as the investigations have advanced, the simplicity appears as merely one of words and not of fact. Before a single one of the infectious diseases can be understood from the modern point of view, we must have further knowledge upon phagocytosis, chemio-taxis, positive and negative, the effect of the various tissues of the body, as blood-serum, upon the micro-organisms in health, and the chemistry of the ptomaines, leucomaines, and tox-albumins must be an actuality. As advances in any of these directions occur, it is possible to hope for at least a partial solution of some of the problems of how to treat disease specifically; but any such solution must be based upon more knowledge than we have now.

Huepp¹ states some of these problems in an article upon the investigation of disease, and the points derived therefrom, of value in treating and healing infectious disease. He lays especial stress upon the fact that it is not only the bacteria that produce infectious disease, but also those qualities that are empirically called "predisposition" and "immunity," as well as social and hygienic surroundings. Speaking of the requirements in a medicament to be used in an infectious disease, he sets them down as (1) that it must have a chemical action upon cell protoplasm; (2) that it must have a specific affinity for the tissues against which it is directed, and (3) that this affinity must of course be the same as that manifested by the infections principle and its products. The greater portion of his article lays especial stress upon tuberculosis, and from the work done in this direction as well as others, he draws the conclusion that after all, the best method of treatment we yet have, is to build up the body and improve the hygienic conditions. He looks forward to the possibility of obtaining some special agent to use in particular cases, but holds out the old warning that we must not expect to diminish the sum total of mortality, although we may be able to affect one disease, as has already been the case with small-pox, since the introduction of vaccination. An extremely important point that he makes is, that it should not be expected that we can ever secure a material to act quickly against all diseases, for the reasons that will easily occur to any one. If anything is secured in certain of them, it will be something that will act so slowly as to make the effect of any one dose practically imperceptible, and whose manner of cure will be almost a reversal of the process by which the disease

¹ Read before the Boston Society for Medical Observation, December 7, 1891.

² Berl. Klin. Woch., No. 11, 1891.

made itself manifest. So much for the general considerations.

This is not the place to speak of the mass of work that has already been done toward solving the problems spoken of, as being before us, but one or two exceptions may be made, notably in the case of Mya and Sanarelli,³ who, in a very recently published article, give the results of a large amount of work upon the influence of a high degree of "hematolysis" as a favoring cause of the infectious diseases. Using a blood-destroying agent, acetylphenyl hydrate, and various injections into rats, guinea-pigs, pigeons and dogs, and employing anthrax bacilli and pneumococci as their test-agents, they come to the conclusions that (1) destruction of the blood-corpuscles as well as other well-known causes (bleeding, weakness, fasting, etc.,) favors the beginning and course of an infectious disease in animals that are possessed of only a relative immunity against this disease under natural conditions. (2) That the same destruction of the blood-corpuscles does not, however, favor infection in animals that have a high degree of immunity.

In the line of the same general subject, but in a different direction are the researches of Ferranini,⁴ in which he attempts to determine the antiseptic dose of substances that are often used for their antiseptic action. This antiseptic dose, he calls that amount of the material under investigation that, in one litre of fluid, will prevent the transformation of blood-fibrin into peptone under the action of chlorhydrate of pepsin. It is interesting to know that he found non-antiseptic, even in a proportion as high as five parts in one hundred, such substances as iodoform, boric acid, sulphate of quinine, turpentine, iodol and naphthol-B. He lays especial stress upon the advisability of those attempting to secure stomachic and intestinal antiseptics being also familiar with the antiseptic action of the substances used.

Ometschenko⁵ gives the results of many experiments as to the effects of certain of the ethereal oils upon the bacteria of typhoid, tuberculosis and anthrax. His conclusions are of importance as being steps in a direction giving much promise for further investigation, both experimentally and clinically. Some of them are: (1) The vapor of the ethereal oils has a definite disinfective action. Curiously enough he puts oil of cinnamon, oil of fennel, and oil of lavender at the head of the list; (4) The protoplasm of the bacteria undergoes a specific change, as is seen by their behavior towards aniline colors and the granulation of the protoplasm; (8) emulsions of ethereal oils diminish their volatility; (9) air only takes up a certain quantity of the vapor, and violent forcing does not increase this quantity. The air must be renewed as often as a knowledge of the amount it takes up and its effect upon the specific micro-organism makes necessary.

Such experiments as these are of the greatest importance, in the special subject under consideration this evening, even in view of the work of Korkunoff⁶ negating the supposition that infection can take place through the normal intestinal wall.

The general influence of surroundings upon the attacks of infectious disease is well illustrated by Canalis

and Morpurgo⁷ in their work showing the effect of such influences, notably in one instance. Experimenting with pigeons, that are immune to anthrax under normal conditions, inoculations of the bacilli were made and at the end of eight days fasting was enforced. As soon as this was done, the birds died of anthrax, showing not only that the bacilli lived in their bodies during that time, but that the influence of hunger had a very remarkable effect in diminishing the immunity of these birds against the attack of the micro-organisms.

Coming now to work bearing more directly upon the subject, some of the most important that has been published may be very briefly summarized.

Cantani⁸ in an interesting article upon intestinal antisepsis, makes the fundamental statement that the various bacteria in the intestinal tract of the living body cannot be killed by any chemical agent with which we are yet familiar except in the rarest cases, and that for the present, attention must be directed towards retarding the development or decreasing the numbers of those present. The two roads by which materials with these objects in view can be introduced are the mouth and the rectum. If the first be chosen, the results are extremely uncertain, for the reason that the material employed must either be unaffected by the gastric juice, or else it must be soluble, and therefore lose a large part of its local effect by reason of absorption. Administration by the rectum, is therefore the shortest and most certain method, for a certain distance. By this means we have control of the bowel as far as the fluid or other material can be passed, and may govern the condition of things as we choose, at least, for limited periods of time. For this purpose, the author recommends tannin and carbolic acid especially. The development of cholera spirilla was retarded by the use of a tannin solution of .5 per cent. strength, and they were mostly killed after six hours; they were completely destroyed after one and one-half hours contact with a 1.5 per cent. solution.

P.-Lasky⁹ points out that the fermentative changes in the intestine represent more than the mere presence of bacteria and means to get rid of them. He showed by experiment that the bacterium aceticum, normally present in the intestine, destroys certain of the bacteria of green diarrhea. Therefore it is quite possible in certain cases, that a powerful anti-bacterial treatment, even if successful in destroying germs, may be undesirable, in that it interferes with the conflict between different forms of micro-organisms. Woodbridge¹⁰ reviews the work upon intestinal antisepsis, and speaks of that tending to show the value of creolin and naphthol-B.

We are familiar with the mass of assertion in regard to the experimental and clinical value of various of the coal-tar colors, and if certain of the observations reported are true, it will hardly be possible to agree with the editorial remark of the *Boston Medical and Surgical Journal* (vol. cxii, p. 18), that "attempts to control the course of typhoid fever by antisepsis of the bowel will be ultimately abandoned as irrational and unavailing." If the day should dawn upon which we could feel that there had been secured the material effective in the arrest or destruction of the typhoid bacillus in the body without injury to the patient, then

these methods may be considered out of date, but until then something of the sort spoken of seems to be the only directly effective means at our command.

FAT EMBOLISM.¹

BY W. F. WHITNEY, M.D.

THE following case of comminuted fracture of the femur, with death on the fourth day, for which no evident cause was found, aside from a fat embolism of the lungs, leads to a consideration of how far we are justified in regarding this as an adequate cause of a fatal termination.

A male, sixty-two years old, entered the Massachusetts General Hospital in the service of Dr. Maurice H. Richardson, with a fracture of the right femur, from an elevator falling upon him two hours before.

During the first two days he was reported as comfortable, but having had no movement of the bowels was given a saline cathartic on the second day, without any effect.

Up to noon of the third day he had no defecation, and at that time his bowels began to swell, and increased till four P.M., with diminution of the area of liver dulness. An enema caused a dejection of the contents of the rectum. At one P.M., vomiting commenced and continued intermittently till eight P.M. Vomitus was very dark brown, but without fecal odor. No gas passed either way. Urine normal and passed without difficulty. On the fourth day there were the same general symptoms. Vomitus of a black color. Abdomen aspirated and a clear straw-colored serum obtained.

Conscious, but restless. Suffered no pain, his only complaint was of difficulty in breathing. Pulse went up during the day while the temperature fell. Died suddenly at quarter-past five P.M.

	Aug. 31.	Sept. 1.	Sept. 2.	Sept. 3.	Sept. 4.
Temperature	99°	101.5°	100°	101°	98°
Pulse	60	70	70	90	130

Autopsy by Dr. W. F. Whitney, eighteen hours after death. Body of a large man. Rigor mortis present, and some lividity of the dependent portions of the body. The right foot was everted, the leg shortened, and there were numerous ecchymoses over the ankle and middle of the thigh. Upon opening the latter a comminuted fracture of the femur in its middle third with considerable laceration of the muscles was found.

Head not opened.

Thorax, pericardium and heart were normal.

Both pleural cavities contained a little clear fluid with some old adhesions of the surface of the right lung.

The lungs were partly retracted, the upper lobes dry, the lower lobes of a dark bluish color, and considerable dark thin fluid escaped from the cut surface. There was no evidence of consolidation anywhere. Microscopic examinations showed the small vessels extensively plugged with a highly refracting fluid substance (fat).

Abdomen. The peritoneal cavity contained a small amount of fluid. The peritoneum was injected, but had everywhere its normal lustre, nor was there any-

where evidence of a deposit or exudation of any sort upon the surface. The stomach was filled with a dark, foul-smelling fluid, and this could be traced to the end of the jejunum. Beyond this point the intestines contained a little yellowish feces. The inner surface of the stomach was marked here and there by a network of injected capillaries and a few superficial losses of substance with a hemorrhagic infiltrated edge.

The intestines from the stomach to the rectum were extremely distended with gas.

The spleen was of normal size and pale. The kidneys and liver were pale, slightly opaque, and upon microscopic examination the cells were found to be markedly granular.

Before considering this case further it will be well to recall, briefly, what has been brought out from the study of the subject.

Magendie, in 1827, was the first to prove experimentally that oil injected into the veins of an animal would produce death. But it was not till 1862 that Zenker called attention to the presence of fat in the vessels of the lungs in some cases of death after fracture of the leg; and it then came to be regarded as a sufficient cause. But gradually, as the infectious process with which it was often associated were better understood, the conviction grew that fat embolism of the lungs alone was not sufficient to produce death, and that its action on centres more remote must be considered. By far the most thorough and exhaustive study was made by Scriba,² and published in 1879. And since then but little has been added to our knowledge. His work consisted in experiments on animals and the analysis of cases by the light of the results thus obtained.

The problems which he proposed were:

(1) How much fat is required to kill? (2) In what way does it act? (3) How is it eliminated?

In answer to the first he found that in order to kill an animal by fat embolism a quantity is necessary varying with the force with which it is injected, and with the distance of the point of injection from the heart. But in no case was it less than three times the amount of fat contained in the entire femur of the animal.

His conclusion as to the mode of action is: that death after aseptic fat emboli occurs only from large numbers in the brain and spinal cord, and in consequence of the arterial anemia and the resulting disturbance of nutrition.

Of course, any deleterious action on the heart and lungs had first to be eliminated. In regard to the former it was done by direct observation on the living animal, and a comparison of the length of time that the heart of an animal killed by fat injection reacted to stimulus when compared with the normal. From these experiments he found that the disturbances which are caused by the entrance of oil into the heart are only to be found in the increase of the quantity of fluid of which the heart has to take care. And the speedy death is caused neither wholly nor in part by paralytic of the heart, and that aseptic fat has no permanent influence on its action.

As for the lungs, experiments have shown that five-sixths of the arteries must be tied before an animal is killed, and that at least three-quarters of the entire pulmonary system shut out before the arterial tension in the body is the least altered. Therefore he reasons that in man there is never such a degree of embolism

¹ Read before the Boston Society for Medical Observation, December 7, 1891.

² Deutsh Zeitsch. f. Chirurgie, Bd. 12, s. 118.

of the lung capillaries that death must result; and he was never able to produce this in animals even by direct intravenous injection.

On the other hand, it is the fat which has passed the lungs and reached the central nervous system that is the cause of death.

In answer to the third question, his experiments and clinical evidence (to be mentioned later) point to the kidneys as the organs by which the greater part is eliminated. A smaller part is undoubtedly burned up in the system.

Of the symptoms noted, one of the most striking was the constant fall in temperature. When large quantities of oil were used this fell 9.5°C . in nine hours in one case, and in another 7°C . in one and a half hours. In those cases in which death did not result, the return to normal was accomplished in about the same time as the fall.

Another symptom was dyspnea, due to the loss of oxydation of the blood. This often was only transitory; but may be persistent and very urgent.

Slight hemoptysis, due to infarction, has also been noticed. Edema of the lungs was never seen in any of his experiments although its occasional occurrence may not be denied.

The most important clinical symptom of fat embolism is the presence of oil in the urine. He examined this from a number of fracture patients, and was able in nearly all cases to demonstrate it to a greater or less degree. The oil did not appear in but a few cases as a continuous sheet on the surface, but as a whitish, slimy cloud in the upper part, at times three centimetres thick. It would not be recognized as fat by the eye alone; but with the microscope there were seen numerous very small, round drops, which were highly refracting, and had a fine dark border. At first, they might be regarded as bacteria, but the reaction with osmic acid and recrystallization after extracting with ether proved their true nature. A curious fact was ascertained, namely, that the elimination is not continuous, but interrupted. Fat was first noticed on the second, third and fourth days after the accident, then again from the tenth to the fourteenth day, and rarely once or twice again with intervals of from six to ten days between.

A marked pallor of the skin and mucous membranes was noticed in all the animals experimented upon.

In the fatal cases there was great irregularity of respiration, marked at the end by superficial respiration alternating with deep and spasmodic inspiratory movements.

These again point to anemia of the brain, and death followed from paralysis of the respiratory centres, while the heart still continued to beat.

He last of all analyzed one hundred and seventy-seven reported cases, and found only fourteen in which death could be attributed to this cause alone, according to his standard.

The clinical picture which he draws, is as follows:

- (1) Certain proof of periodic occurrence of fat in the urine.
- (2) Transitory attacks of dyspnea.
- (3) At times occurrence of slight hemoptysis without fever and usually without dulness or rales.
- (4) Diminution of temperature.
- (5) Irregular action of the heart.
- (6) Collapse, with extreme pallor of the skin and mucous; at first, shallow respiration, at times broken

by a deep sighing inspiration, later, Cheyne-Stokes' phenomena.

(7) Spasms of different kinds or paralyses, which in the experiments were usually bilateral.

(8) Diminution of reflex irritability.

If the history of the case given at the beginning is now reviewed, it is hardly just with data given to ascribe the death to fat embolism alone.

The death within the first week, the dyspnea, and the rapid fall in temperature in the last few hours are the clinical features which can be best brought in accordance with picture as drawn above. On the other hand, the fever during the first three days, the paralysis of the intestines with extreme gastric disturbance (although these two latter might be of central nervous origin) would rather point to a septic infection. This, however, had failed to localize itself either in the spleen or serous surfaces. The only positive evidence were the fat emboli in the lungs. It is now seen that the failure to examine the brain was a grave omission.

With the data at hand, the case is best regarded as one of septicemia with fat embolism, in which the fatal result cannot be attributed to either alone but to both as factors.

The two important points brought out by the above consideration, are:

(1) On the clinical side, that the urine of patients with fracture should be carefully watched from the second to the fourth day for the presence of free or emulsified fat.

(2) On the pathological side, that unless found in the brain the cause of death cannot surely be ascribed to fat embolism.

OBSERVATIONS ON ALBUMINURIA IN SCAR-LATINA.

BY JAMES W. DUDLEY, M.D.,
Medical House-Officer, Boston City Hospital.

(Concluded from No. 6, page 146.)

TAKING the above standard as to the presence of nephritis there were found 18 cases out of the whole 100 which developed nephritis; that is, in 18% of the urines were albumen and casts found. Of these, eight were of the more severe type, and 10 the variety spoken of as catarrh.² One case only began as a catarrh and later developed into a severe nephritis. The catarrh was first noticed the third day of the disease, and on the eighth day, as desquamation was getting well-established, the albumen increased in amount, and epithelial and blood casts and free blood appeared. In this case the high temperature of the eruptive stage was prolonged evidently by the nephritis. This case is interesting as showing how the catarrh may terminate, a method of termination, however, which seems to be rare. The case is classified in the following statistics as one of severe nephritis.

Scarlatinal nephritis is said to occur most frequently between the ages of five and nine.³ The age of the patients having nephritis in this series of cases is shown

² As has been said it seems impossible to draw a *definite* line between mild and severe nephritis from the urinary examination, but for practical purposes it has seemed best to speak of such cases as presenting normal or high-colored urines with a trace of albumen and a few hyaline or granular casts only. In research, and those in which any way gave evidence of more serious renal changes, such as blood or fatty elements, as the more severe form of nephritis. Only in one or two cases was there difficulty in deciding which variety the case should be called.

³ See Guy's Hospital Reports, vol. xxxi, 1889.

below, together with the number of cases occurring at the several ages.

SEVERE NEPHRITIS.

Age	4 or less	4-8	8-16	Over 16
No. of cases . .	4	2	0	2

RENAL CATARRH.

Age	4 or less	4-8	8-16	16-20	Over 20
No. of cases . .	3	2	0	1	4

Total cases, 18.

It will be seen that the largest number of cases of severe nephritis occurred in patients four years of age or under, and six of the eight were persons not over seven years of age. The other two cases were in adults (age nineteen and thirty-four). The period from eight to eighteen inclusive, was free entirely from severe nephritis. The mild variety was found in adults and children with equal frequency, five being under seven years old and five over sixteen. Young children, four or under, presented this complication less frequently than did adults over twenty. This is in marked contrast with the more severe variety to which children appear to be much more liable. The absence of any form of nephritis between the ages of eight and sixteen inclusive, is noteworthy. The complete absence of nephritis during this, the most vigorous period of childhood, is doubtless a mere chance in this set of cases, but that there is a diminished liability for children during this period of life to develop nephritis is at least strongly suggested.

It would seem improbable that sex could have any influence, predisposing or other, in the development of nephritis. It is, however, worthy of observation that the majority of cases of severe nephritis occurred in the male sex, 62.5% of the severe cases being in males. Of the cases of simple catarrh the majority occurred in females, 30% only being in males. The only suggestion which this observation seems to offer is that scarlet fever is possibly more apt to be a severe disease in females.

The time of year does not seem to have very much influence in the causation of nephritis. It was slightly more common during December, January and February than at any other time. Renal catarrh seems not to have been at all influenced by season. The total number of cases in the hospital at any one time made no change in the proportion of cases developing nephritis. Unfortunately, however, the time covered by this series of cases did not include any periods when scarlatina was especially frequent in the community, and therefore the influence of epidemics in the frequency or severity of nephritis cannot be stated.

The fact, so frequently observed in regard to scarlatinal nephritis, that no dependence can be placed on the severity of the fever as to the probable development of nephritis is amply borne out by these cases. In fact, so far as they show, severe nephritis is more apt to follow a mild case of scarlet fever than a severe one. In but two of the eight cases of severe nephritis was the temperature above 101.2° at entrance (time of entrance being on the average the second or third day of the rash), and the average temperature for all the cases of nephritis was 101.53°. This is in marked contrast with the cases of renal catarrh, in which the

temperature for the whole number averaged 102.6°. In but one case was it less than 101.4° at entrance. Thus mild nephritis or renal catarrh does seem to be influenced markedly by the severity of the fever, being probably a part of the disease itself. The contrast in the severity of the disease in which the two forms of nephritis developed is shown as follows:

Severe nephritis, 75% in cases with a temperature of 101.2° or less.

Renal catarrh, 90% in cases with a temperature of 101.4° or more.

In estimating the day at which the nephritis began, the beginning of the eruption has been taken as the first day, on account of the impossibility in many cases of ascertaining definitely any symptoms occurring earlier. The time at which the nephritis first made its appearance is shown below:

NEPHRITIS.

Time of nephritis . .	1st week.	About end of 3d week.	Beginning of 4th week.
Number of cases . .	3	4	1
Desquamation . .	Not begun.	In progress.	

CATARRH.

Time of catarrh . .	1st week.	Late in 2d week.	Very late (3d week).	Unknown.
Number of cases . .	5	2	1	2
Desquamation . .	Not begun.	During early part.	Finished.	

Nephritis, therefore, occurred most frequently about the end of the third, or beginning of the fourth week, during the period of desquamation, and in no case beginning with the beginning of desquamation, not rarely, however, it starts during the first week, before desquamation has set in. The most common time for catarrh is during the first week, when the temperature is high and the disease active.

The duration of the nephritis in those cases where the actual time was observed, presented some degree of regularity. In half the cases it lasted thirty to forty days. One well-marked case only seven days, one about twenty. The duration of the others was not observed. Five weeks, therefore, seems to be about the average length of time covered by many cases. No regularity at all is shown by the cases of catarrh. They lasted from four to forty days.

The relation of albuminuria and nephritis to some of the other common complications of scarlet fever is worthy of note. The most common of all the other complications is *otitis media*. This occurred in 10% of the cases. In five the left ear being the one affected, and in four the right, and in one both ears. The duration of the otitis was extremely variable, as also was the time of its beginning. In half the cases the ear trouble was first noticed twenty-five days or later after the beginning of the fever. The average duration was twenty-seven days. The actual length of time varied from twelve to fifty-three days. Out of all the cases of otitis 60% presented albuminuria, and 20% only had nephritis. In but one case was renal catarrh present. It has been said that in cases having both nephritis and purulent disease of the mid-

dile ear the urine clears up as the otitis subsides, but in the limited number of cases with both observed in this series this coincidence, if such there be, was not found. It is interesting to note in passing that the majority of the cases of otitis (70%) developed in cases with comparatively mild fever, that is, in those with a temperature not over 102°. Otitis seems, therefore, like nephritis, a complication quite as apt to occur in mild as in severe cases of scarlatina.

Diphtheria was said to be a complication in six cases. Whether these were all cases of true diphtheria developing upon scarlet fever, the writer cannot say. At any rate, they were characterized by very severe angina and well-marked false membrane. In five of these, or 83%, there was albumen in the urine; in but one case was nephritis present.

Pneumonia occurred in three cases, two of which ended fatally. All presented albuminuria. Nephritis was not observed in any of them.

Severe abscesses of the neck were present as a complication in three cases. In one nephritis occurred, in one simple albuminuria, and in one the urine was normal throughout.

Out of three cases of *inflammation* of one or more joints, one had nephritis, one catarrh, and one no albumen.

Measles complicated two cases, beginning the twenty-third and twenty-fourth days of the original disease. Albuminuria was present in one, nephritis in neither.

Summing up, in brief, the results regarding complications, it is found that 25 out of the 100 cases presented some of the above complications, not including nephritis. Out of these 72% had albumen at some time, 20% had nephritis, 12% had catarrh, 40% had simple albuminuria, 28% had no albumen at any time. Complicated cases, therefore, present a much larger proportion of albuminuria and severe nephritis than do simple cases, while the proportion of cases with catarrh is not materially changed. It is noteworthy, also, that 63% of the cases of severe nephritis were in patients also having some of the above complications.

Scarlatinal nephritis seems to differ in one very important respect from acute nephritis of other origin.

So far as the writer has observed it is quite apt to develop quickly without giving any signs of its presence in the appearance of the patient. Edema is apparently not a common accompaniment in the earlier part of the case. Nearly all the cases in this series were found by the urinary examination before any other evidence of their presence had been observed.⁴ Occasionally, a slight rise in temperature accompanies the onset of the nephritis. Close and constant attention to the urine is therefore the only way to make sure that nephritis is not developing.

The writer regrets that he is unable to say anything about the *prognosis* of the nephritis. In all but four of the cases of scarlet fever here recorded, recovery took place. In none of these four fatal cases was nephritis detected. Death in two was due to pneumonia, in one to diphtheria. In none of the cases did nephritis become chronic. The total number of cases of nephritis is, however, too small to be of any positive value as regards prognosis.

The results obtained from the comparison of these 100 cases of scarlet fever may be summed up as follows:

⁴ See British Medical Journal, 1889, ii, p. 657.

ALBUMINURIA.

Albuminuria was present at some time during the disease in 49% of all the cases; it was slightly more common in males than in females. Early albuminuria maintains a pretty constant relation to temperature, being of much more frequent occurrence in cases with high temperature. It was present much more frequently in adults than in children when the temperature was the same, and of almost universal occurrence in adults with high temperature; it does occasionally occur in cases with a low temperature; over-crowding and poor ventilation were not factors in its production. Early albuminuria occasionally is caused by or leads to renal catarrh, very rarely to severe nephritis; catarrh is not apt to be developed into severe nephritis.

NEPHRITIS.

SEVERE NEPHRITIS.

In 8% of all cases of scarlet fever.

Is most common in children under 9 years of age.

Least common time, 8 to 18 years of age.

60% in males.

Rather more common in winter than in summer.

Is not influenced by the number of cases in the hospital (over-crowding and poor ventilation).

Is as common after mild as after severe cases of scarlet fever.

Generally begins between third and fourth week of the disease.

Generally during desquamation.

Common duration, 5 weeks.

RENAL CATARRH.

In 10% of all cases of scarlet fever.

Occurs with equal frequency in children and adults.

Least common time, 8 to 16 years of age.

70% in females.

Season has no influence.

Idem.

90% in severe cases.

Most common in first week.

Most common time before desquamation.

No regularity of duration.

COMPLICATIONS.

Excepting renal catarrh, *otitis* is the most frequent complication of scarlet fever, occurring in 10% of all the cases. It is as common in mild as in severe cases of scarlatina. It sometimes begins early, but usually not till the period of desquamation and sometimes very late. Sixty per cent. of cases with otitis have albuminuria, 20% nephritis.

Most of the cases complicated by *diphtheria* present albuminuria. Nephritis is not especially common. Of the other individual complications no summary is needed.

It should be said that the proportion of cases in this series presenting albuminuria is larger than is generally supposed to occur, but the percentage of cases with nephritis agrees very closely with that observed elsewhere.

CUTANEOUS ERUPTIONS IN INFLUENZA.¹

BY CHARLES F. MASON,
Assistant-Surgeon, U. S. A., Fort Washakie, Wyo.

The following cases are cited as a contribution to the literature of that many-sided disease, influenza, particularly as very little has been written about this phase of the disorder:

CASES I and II. A. B., aged six months; first seen January 1, 1892. Mother says child has been sick for several days with fever, cough, vomiting and constipation, and to-day a rash has appeared which she thinks is measles. Upon examination I found tongue thickly coated, chest, abdomen and back covered with

¹ Published by authority of the Surgeon-General.

a discrete eruption, pale, but exactly like that of a mild case of measles, and well-marked broncho-pneumonia; there was high fever, but not having a thermometer temperature was not taken; no catarrhal symptoms; no redness of tongue or pharynx. Influenza was then prevalent; the eruption was the only point of resemblance to measles; there had been no measles within 150 miles of us for many months, and I diagnosed influenza, but nevertheless isolated the patient and took the same precaution as if the disease had been a contagious one. The next day the eruption had spread over the entire body, was confluent and much more vivid except upon the face; other symptoms as before. Though still in doubt, I thought best to treat the case as one of measles, and reported it as such to the Surgeon-General of the United States Army.

The same day, January 2, 1892, a half-breed infant of about nine months was brought to me by its mother, a Shoshone Indian squaw, with exactly the same symptoms except the pneumonia, the eruption being most typical and everywhere confluent. This second case had been brought in that day from a "tepee" on Upper Big Wind River, about twenty-five miles distant, and I was informed by the mother that there were one or two other cases of the same nature in that region.

January 3d, the eruption in both children had almost entirely faded, and on the 4th was gone, without the slightest desquamation.

The second case I did not see after this date, but heard that the child made a good recovery. The first has been constantly under my observation, its recovery from the pneumonia being slow and difficult. In the family of the latter there were two other children, one of whom, with the father and mother, was subsequently affected with the characteristic symptoms of the grip, but without any eruption.

CASE III. Nez-Percé, Shoshone Indian soldier, aged twenty-one and one-half years; admitted to hospital, January 9, 1892. Complains of headache, cough, pains in the chest and debility. Upon examination I found acute laryngo-bronchitis, a coated tongue and a few small papules like those of acne upon face and chest; temperature 100°. The next morning, on visiting the ward, I was astonished to find his face, chest and back covered with discrete superficial vesicles, many of them markedly umbilicated but without inflammatory bases. Temperature: A. M. 99.6°, P. M. 102.8°; eyes slightly injected; complains only of severe frontal headache.

January 11th. Vesicles have become pustular; no new ones; feels much better. Temperature: A. M. 100.8°, P. M. 101.4°.

January 12th. Feels well; pustules rapidly drying up.

January 16th. Spots dried up rapidly, forming thin crusts, which dropped off leaving no scar.

This case so closely resembled varicella that the patient was isolated for several days. However, the soldier had not been absent from the post; varicella had not been heard of in the country for many years, and I considered that disease excluded. The other symptoms were those of the grip, and my experience with the two cases referred to above led me to make that diagnosis here also.

Up to this date, January 25, 1892, I have not seen or heard of any more cases of eruptive disease in this neighborhood; and the Agency physician, who treats a large number of Indians, says he has not met with

any except one case of influenza with a vesicular eruption like the one referred to.

My cases were very puzzling to me at first; but their history, subsequent course, absence of any of the symptoms of the exanthemata except the eruption and fever, and the presence of the characteristic symptoms of grip, the absence of any probable source of contagion, and the fact that no new cases developed, all led me to the inevitable conclusion that the history of influenza has not yet been fully told.

Clinical Department.

THREE CASES OF PUS IN THE FEMALE PELVIS; ABDOMINAL SECTION.¹

BY WALTER L. BURRAGE, A.M., M.D., OF BOSTON.

CASE I. Pyosalpinx. Large tube of pus. S. J., single, a domestic, thirty-two years of age and a native of Nova Scotia, entered St. Elizabeth's Hospital, June 3, 1890. The diagnosis made in the Out-patient Department was retroversion. She was a thin woman, rather pale, and gave a history of chronic dyspepsia. It was questionable whether she had had gastric ulcer a year before. Her general health was poor. The chief complaint at the time of entrance was of frequency of micturition and general weakness. Her catamenia were regular, scanty (only one napkin), and attended by no pain. Local examination showed what appeared to be a large uterus in the third degree of retroversion. The sound was not passed because there was some suspicion of pregnancy. She was treated with packing, and kept under observation until June 23d, when she was anesthetized.

Dr. F. W. Johnson saw her with me then in consultation. We found the mass behind, previously thought to be the fundus of the uterus, to be a cyst the size of a large Florida orange, firmly adherent and resistant, though much less resistant than when the patient was not under the influence of an anesthetic. It had a doughy feel. The uterus was pushed forward and to the right, the sound entered its cavity two and three-quarters inches. There was a nodule on the right side the size of a small duck's egg.

From the situation of the cyst, in Douglas's pouch; from its doughy feel; from the fact that the patient had had no chills, no elevation of temperature since she had been under observation, and from the absence of history of previous inflammatory attacks, it was considered that we had to do with a case of dermoid cyst of the ovary in all probability. It was thought best to keep her under observation, and, if possible, build up her general strength, meanwhile watching the tumor.

After six weeks the tumor had increased in size a little; she had had two slight attacks of pain referred to the lower abdomen, and an elevation of temperature of one or two degrees for a day or two, shortly after the ether examination; the rest of the time the temperature had been normal. In spite of a generous diet and tonics, her appetite continued poor, the bowels were obstinately constipated and her strength not improved. Accordingly the proper course seemed to be to remove the tumor. August 11th, with the assistance of Drs. W. M. Conant, E. L. Twombly and

¹ Read before the Warren Club, Boston, December 1, 1891.

the House-surgeon, I opened the abdomen. Dr. John G. Blake was present. The usual antiseptic precautions were observed. The fingers inserted through the abdominal wound came at once upon a large cyst on the left side of and behind the uterus, very firmly adherent to the walls of the pelvis, and to the uterus. As many as five strong bands of adhesion were ligated with silk and divided, and numberless smaller adhesions were separated with the fingers. After considerable manipulation the cyst was entirely freed and delivered intact through a four-inch abdominal incision. This cyst proved to be a stomach-shaped dilated tube filled with pus. It measured four inches in length, three inches in diameter at its largest part, and contained about eight ounces of pus.

On the right side was a convoluted tube about three-eighths of an inch in diameter, and the ovary, both firmly adherent to the sides of the pelvis and the uterus, and to each other. It seemed at first to be next to impossible to remove the appendages on this side without badly lacerating the soft parts of the pelvis. An attempt was made to ligate the broad ligament from above downward with interlocking ligatures. After a few were tied it became evident that this method would leave a large and clumsy pedicle, besides running a chance of including the ureter, so I decided to tear off the posterior adhesions, pull up as much of the tube, broad ligament and ovary as possible, ligate and remove. This was done accordingly.

The parts were so matted together it was not possible to say whether any portion of the tube or ovary had been left behind. The tube removed presented all the appearances of chronic suppurative salpingitis.

There was considerable venous oozing. The abdomen was flushed with hot water, the cul-de-sac sponged, and a drainage-tube placed in the lower angle of the wound, which was closed with silk, dusted with iodoform, and dressed with baked gauze, strapping, cotton and a binder. Length of operation two hours.

The patient's condition during the operation was poor. She required stimulation several times, but rallied fairly well, however. The temperature was below 100° for the first forty-eight hours, the pulse was rapid all along, being about 120. The tube was removed at the end of twenty-four hours. On the third day the temperature rose a little and vomiting set in. Gas was not passed per rectum for sixty hours. She was given salts and then calomel on the fourth day, without result. She had the anxious countenance noted in cases of peritonitis, and a decidedly septicemic odor was noticeable in the room. The pain was slight. Beginning distension of the abdomen and a temperature of 103.8° in the morning, with regurgitation of dark-colored fluid preceded the fatal issue, which took place from heart failure on the fifth day.

I made a partial autopsy twenty-four hours after death, and found: Marked post-mortem discoloration of the abdomen, lips of wound not firmly adherent, no pus. Incision enlarged upward to ensiform and downward to symphysis. Abdominal cavity and pelvis contained no fluid. Intestines distended with gas and injected, no effused lymph, no adhesions. They contained a small amount of thin brown liquid similar to that regurgitated during life. Walls of pelvic cavity a dirty green color (from decomposition). Nothing abnormal about the condition of either pedicle: no trace of either ovaries or tubes found. The sigmoid

flexure of the colon entered the true pelvis anterior to its normal situation, being at a point half-way between the promontory of the sacrum and the middle of Poupart's ligament. It was glued to the left pedicle and to the edge of the pelvis. The calibre of the gut was not encroached on, and the walls were not injected or thickened. Diagnosis: Atony of intestines from septic absorption.

CASE II. Chronic pelvic inflammation, with abscess discharging into the rectum. Intraligamentous cyst. S. A. U., widow, thirty-two years of age, a native of Nova Scotia, entered St. Elizabeth's Hospital, June 29, 1891. She gave the following history: Family history negative. She never knew what it was to be sick, with the exception of a slight attack of inflammation of the bowels fifteen years ago, until she had the grippe in 1889, and since then she has never been well. Has had three children, no miscarriages. The last child was born fourteen years ago. In October, 1890, she was in the Rhode Island Hospital with an attack of "inflammation of the womb." She was confined to the bed for several weeks at that time, and was told that she had an abscess, and operation was advised. Since then the abscess has discharged into the bowel several times (four or five). She would have sharp pain in the abdomen for several days getting relief finally by the passage of an ounce or two of matter. The last discharge was two weeks before entrance, at the time of the catamenia, a nearly constant discharge since with so much pain that she is "all tired out," as she expresses it. Bowels inclined to constipation. Much trouble with accumulation of gas in the intestines, and feels a "lack of power" in the rectum. The catamenia were established at twelve and one-half years; regular every four weeks up to two years ago; since then every three to four weeks; of three to five days' duration, and six to ten napkins at first; lately, of seven to nine days' duration, and fourteen to eighteen napkins are used. General strength good. Patient of large frame, well developed and nourished. Says that life has become a burden to her because of the repeated attacks of pelvic pain and her consequent inability to pursue her daily occupation, that of seamstress, for any length of time.

Physical examination showed a large mass of inflammatory exudate nearly filling the pelvis, and surrounding the rectum so as to encroach on its calibre about three inches up from the anus; the uterus three inches deep, lying on top of the exudate and in front. She was kept quiet, given two large hot douches a day, laxatives for the bowels, and a general diet, and every other day the vault of the vagina was painted with Churchill's tincture of iodine.

At the end of a month, during which time she had had on two occasions a discharge from the rectum of mucus streaked with blood and accompanied by pain, it was decided to give ether and make a thorough examination. The exudate had largely cleared away at this time.

July 29th, Drs. R. A. Kingman and Conant saw her under ether, with me. We mapped out a fluctuating mass the size of a small orange, in the right side of the pelvis, and also an indurated swelling about the size of a lemon around the rectum in the left pelvis. Query whether they were connected or not. The gut barely admitted the tip of the examining finger at the seat of the swelling. An exploratory incision seemed

to offer her the best chances; she readily consented, and the operation was done August 10th. I was assisted by Drs. G. H. Washburn and the House-surgeon. Drs. Kingman and H. P. Jefferson, of Lowell, were present. The incision was three and one-half inches long. The abdominal walls were about three-quarters of an inch in thickness. Two fingers inserted in the abdomen revealed the presence of a cyst in the right pelvis firmly bound down, and apparently under the peritoneum: the convoluted right Fallopian tube, normal to the feel, could be made out lying on top, the ovary was not felt. The uterus was in the first degree of retroversion, though pushed forward as a whole, and adherent on the left side to an indurated swelling about the size of a small lemon. The cul-de-sac was obliterated by adhesions.

On the right side I thought I had to do with either an intraligamentous cyst, a simple cyst of the broad ligament, or pus burrowing beneath the peritoneum, and in the folds of the broad ligament. The uterus was partially freed from its adhesions after considerable manipulation, and it became possible to push a finger into the cul-de-sac. With Dr. Kingman's finger inserted in the rectum it was plain to the examining finger in the abdomen that the gut passed through the indurated mass. On Dr. Kingman's withdrawing his finger, pressure in the cul-de-sac caused pus to flow from the anus.

It being impossible to remove the swelling on the left without badly tearing the gut, and as a resection low down in the pelvis is a difficult procedure, even when there are no adhesions, the question arose, what should be done as to the cyst on the right side. If a cyst of the broad ligament, it would cause her little discomfort, and if emptied might not refill. As it was so deeply situated that it would be out of the question to open by the abdomen and stitch to the lips of the wound, and as enucleating would, if successful, leave her with the chief source of her trouble still untouched, and at the same time lessen her chances of recovery, more particularly if the cyst should contain pus, I decided to break up all possible adhesions about the uterus and the inflammatory mass, close the abdomen, and aspirate the cyst per vaginam. Accordingly the toilet of the peritoneum was made, the wound was closed with silkworm gut sutures and dressed with aristol, baked gauze, strapping and a binder. No drainage.

With a finger in the vagina as a guide, an aspirating needle was plunged through the cul-de-sac into the cyst, and about an ounce of clear, odorless, straw-colored fluid that contained one-half per cent. of albumen was obtained. The bladder was catheterized and the patient put to bed in good condition. There was a little venous oozing from the needle puncture in the vagina. Time of operations, one and one-half hours.

The convalescence was uneventful. Gas was passed in fifteen hours, the bowels moved naturally after a Seidlitz powder on the morning of the third day; the temperature was not above 100.6° at any time, and was not above 99° after the first day.

August 28th there were some fulness and sensitivity in the cul-de-sac. She was put on douches, and the vault of the vagina was painted with iodine. Early in September she had diarrhoea associated with a discharge of pus. Dr. Kingman, under whose care she came after September 1st, treated her with packing.

October 3d, then having left the hospital, she re-

ported to me that on moving about she had occasional pain of a throbbing character in the right groin. Bowels regular and she had a more natural feeling in the rectum. By vaginal and rectal examination no induration to be felt on the left side, and lumen of gut not narrowed. On the right side the cyst had filled again and was the size of a duck's egg. Uterus forward, fairly movable, two and three-quarters inches deep.

November 5th, she said she had had "labor pains" early in October; pains lasted an hour and a half and were eased by a very hot douche. Three or four days subsequently the catamenia came on. More flow than usual. Has gone back to work. Hasn't felt so well for over two years.

November 15th. Treatment with vaginal galvanism begun.

November 29th. Has passed through a menstrual period of four days without any pain; five towels. Mass much smaller, no fluctuation, no sensitiveness. Much pleased at her improved health.²

CASE III. Acute pelvic inflammation. Abscess of ovary. E. A. F., twenty-four years old, married, a native of Nova Scotia. She entered St. Elizabeth's Hospital July 14, 1891, complaining of severe pain across abdomen accompanied by fever and loss of strength. This was a well-developed, fairly-nourished woman, somewhat anaemic, and of a neurotic temperament.

Examination of the abdomen and vagina revealed abdomen a little distended, walls very tense and the entire pelvis filled with hard, unyielding inflammatory exudate. On the left side there was an indistinct elevation of the mass into the abdominal cavity. Sensitiveness to examination not marked. Temperature 100°. The exudation was of exceptional size and hardness.

The patient gave a history as follows: Married seven years, but never pregnant. Never well since her catamenia were established at fifteen years of age. They had been regular every four weeks, but accompanied by fainting spells and pain in the back. Usually confined to the bed for the first two days of the sickness. A profuse flow, less in quantity of late, about twelve napkins the first three days, then a few for the remainder of a week. For the last two years she has had several slight attacks of pain in the abdomen, the pain never harsh enough to confine her to bed. Has always had a leucorrhœa, and has suffered with constipation. She was seen at the out patient department of St. Elizabeth's in June, 1889, and a diagnosis was made of retroversion; left ovary low down and sensitive.

June 19, 1891, her menstrual period being then due, she was seized with excruciating pain in the lower abdomen. There was no apparent cause for the attack. The flow began shortly and was very profuse. From this time until she entered the hospital, July 14th, she had suffered with almost constant pain and fever, and had been treated by rest in bed, hot douches, poultices to the abdomen, and morphine suppositories *pro re nata*. At entrance she was put to bed, given

² February 13, 1892. Mrs. U. had twelve treatments with galvanism, the current being 10 milliamperes. December 21st, nine were negative and three positive, the vaginal electrode being placed against the cyst; twenty to thirty milliamperes; sittings of six to ten minutes twice a week.

January 25th, when she was last seen, there was nothing to represent the cyst but a small amount of non-sensitive thickening in the cul-de-sac. She was working at her trade, and felt well in every way.

two prolonged hot douches a day, and every other day the vaginal vault was painted with Churchill's tincture of iodine. The bowels were kept open with saline laxatives, and antipyrine, with an occasional opium suppository, administered for pain.

She remained in the hospital a few days only, owing to homesickness. I saw her at her home during July and August, and continued with the treatment just outlined. I have the following notes of her condition during that time:

July 18th. Temperature by the vagina 102.6°. More pain; no chills.

August 1st. Pain less. No temperature by the vagina for the last week. Less induration in the pelvis. Is taking two grains of quinine t. i. d., and a good amount of liquid and semi-solid diet. Sitting up a short time daily.

August 11th. Was called to see her on the night of August 8th. It seems that while sitting up she had been seized with a gripping pain of great severity in the right abdomen; she partially lost consciousness for a few moments. Her mother, who was present, described a marked rigor and gasping for breath, with blueness of the lips. The whole attack lasted only a few minutes. On my arrival, an hour or so later, she was feeling weak, but in other respects as before. Temperature and pulse normal. Nothing developed by a careful vaginal examination. Heart and lungs negative. Never had a similar attack before. She attributed the disturbance to having eaten baked beans contrary to orders.

August 21st. The induration in the pelvis has been clearing up all the time and there seems to be coming out of it in the left side a separate mass the size of a small cocoanut. She had her catamenia from August 14th to 21st, the first since June 19th. Much less pain, but more flow.

August 25th, Dr. F. W. Johnson saw her with me in consultation. Under ether we made out a mass with irregular outline, size of a small cocoanut, in the left side of the pelvis, and pushing the uterus, which was three and a quarter inches deep, well to the right. Mass firmly adherent to the uterus along its right margin, more firmly below than above. A small body the size and shape of a bullet's egg, in the right side of Douglas's pouch. Diagnosis: Cyst of ovary or fibroid; salpingitis. Advice: Exploratory laparotomy.

The patient entered St. Elizabeth's again, and August 31st, with the assistance of Dr. Conant and the House-surgeon, I opened the abdomen. Dr. Johnson was present. An incision three inches in length was made in the usual situation after due antiseptic precautions. The abdominal walls were very tense, and there was considerable oozing. The omentum was lightly adherent to the parietal peritoneum. The large mass on the left was found to be adherent to all the surrounding structures. Many of the adhesions were fresh and easily separated; there were no strong adhesions to the intestines. Two cysts as large as English walnuts, with transparent walls and clear, mucilaginous contents, presented on the surface of the mass. These undoubtedly caused the irregular outline noted at the ether examination.

In the cul-de-sac on the right side, could be felt the ovary, size of a hazelnut, and the tube, size of one's little finger, both bound down firmly. The adhesions on the left were broken away gradually and an attempt made to deliver the cyst. When nearly out it rup-

tured, giving exit to about four ounces of what appeared to be pus. It was of a gelatinous consistency and odorless. Some of it got into the peritoneal cavity. A pedicle formed by the broad ligament and adhesions was included in a Dawson clamp, ligated, and the cystic mass removed. The ovary and tube on the right side were freed from adhesions, raised into the wound, the broad ligament clamped close to the horn of the uterus with Spencer Wells bent forceps, ligated, and the appendages removed. The fundus of the uterus was left in good position, forward, and apparently retained there. There was very little oozing. The abdominal cavity was thoroughly irrigated with hot filtered water in which was a little salt, the cul-de-sac sponged dry, and a drainage-tube left in place. The abdominal wound was closed with silk, dusted with aristol, and dressed with baked gauze, cotton and strapping. No binder was used. Time of operation, three-quarters of an hour. Patient put to bed in good condition. She reacted well. The temperature went up to 100.2° on the second and third nights, after that it was not above 99°. Pulse 70 to 80. Gas was not passed until fifty hours. No nourishment for forty-eight hours. Abdomen flat all the time. The bowels were moved on the third day only after the exhibition of salts, calomel and castor-oil. She was annoyed by obstinate constipation for several weeks subsequently. The tube was removed in twenty-four hours, the gauze in it being soaked with a little serum, and the opening in the wound closed with a stitch left loose for the purpose. The remaining convalescence was uneventful. She left the hospital at the end of September in good condition. Vaginal examination, September 26th, showed the uterus in good position and no evidences of inflammatory effusion in the pelvis. I have heard that she has been in good health since.

Dr. F. B. Mallory, to whom the specimens removed were submitted for examination, reports: Chronic ovaritis, with abscess formation. Dr. Whitney, who kindly looked over the specimens also, agreed with Dr. Mallory that neither Fallopian tube was diseased, beyond some external thickening due to the surrounding inflammatory action.

My object in reporting these cases is to emphasize the difficulty that attends the diagnosis in similar conditions. I know of no affections in the domain of gynecology where the symptoms and rational signs are more misleading.

In pelvic abscess of acute character the diagnosis may be made with comparative ease. By pelvic abscess I refer to a collection of pus originating in the cellular tissue about the uterus. On the other hand, when the condition is chronic and there is pus within or outside of the peritoneum; if within, from a suppurating ovary, hematocoele, extra-uterine fœtation or a leaky tube walled off by circumscribed peritonitis; if without, from a peri-rectal abscess or an iliac or psoas abscess burrowing in the pelvis, we are apt to find features that lend much uncertainty to the diagnosis.

Case I illustrates how little general disturbance may be caused by the presence for a considerable time of a large quantity of pus in a pyosalpinx. There were no chills, no fever, no sweating, no recurrent attacks of peritonitis, and the mass was not the characteristic tense, tender and fluctuating sausage-shaped swelling of the text-books. The chief symptoms were frequency of micturition and general weakness.

In Case II we have an instance of a peri-rectal abscess with manifest symptoms associated with a cyst of doubtful character on the opposite side of the pelvis, the diagnosis being made clear only by operation. One interesting feature of the case was the rapid disappearance of the abscess and the surrounding inflammatory thickening.

In Case III the presence of pus gave rise to unmistakable symptoms up to the time of the subsidence of the inflammatory attack in July. After that time there was nothing to show that she had a good-sized abscess in her abdomen.

It has been my practice during the last three years to make notes of every abdominal operation at which I have been present as soon as possible after the operation, and to fill out the notes, later on, with whatever facts came to my knowledge.

Of 180 cases by various operators, I find that 26 were primarily cases of diseased tubes, as determined at the time of operation; five of the 26 were large tubes of pus. It so happened that I had partial care of all of these five, and was familiar with their previous histories. In only one were there symptoms typical of the presence of pus.

Case III was the second largest pus tube it has been my fortune to see removed intact. The largest was one of two removed from the same patient by Dr. Clement Cleveland, of New York, in January, 1890. The case was reported, and the specimen shown, before the New York Obstetrical Society, and the larger tube is figured in Mundi's edition of "Thomas on the Diseases of Women." It measured six inches in length and three in diameter at its largest part. The other tube, ruptured during its removal, was four inches by three. The patient was twenty-four years old, married one year, and sterile. She had noticed a swelling in the abdomen for six months. Her only complaints, beyond the presence of the swelling, were loss of flesh and sterility. The tumor had been previously diagnosed by competent men as a dermoid cyst or fibroid.

Another of the five cases was one operated on by the late Dr. J. B. Hunter, in November, 1888. The woman was twenty-three years of age, married five years, sterile. She had inflammation of the bowels four years before, and was in bed two months with the attack. She was the picture of health. Her only complaint was dyspareunia. There was a sensitive tumor in the cul-de-sac. A pus tube the size of a fist was removed.

I have the notes of a case similar to No. III, in that a fluctuating tumor emerged from a large mass of exudate. The patient was twenty-eight years old, married ten years; had had four abortions at about two months, probably induced; no children. She had suffered with pain in the lower abdomen for six months previously. The diagnosis was pelvic inflammation and pyosalpinx. At the operation the tumor was found to be a very adherent multilocular ovarian cyst containing clear fluid. There was no disease of the tubes.

THE CORRECTION OF PROSTITUTION.—An association has recently been founded at Buda-Pesth with the objects of combating the evils of prostitution, of redeeming its victims, and of establishing and maintaining a free dispensary for the treatment of poor patients suffering from venereal disease.

Medical Progress.

NOTES OF PROGRESS IN PHYSIOLOGY.¹

BY JOSEPH W. WARREN, M.D.

LYMPH FLOW AND PRODUCTION.

The question of the lymph formation has been studied by Heidenhain.² His results must modify very materially the view commonly held concerning this process. While the origin of the lymphatic system in the spaces in the tissues may be accepted as settled, and while, also, it may be considered as clear that all structures get their material from the blood only by the intervention of the lymph (with the single exception of Bowman's capsule in the kidney), there is no settled view as to how the lymph furnishes the supply of material required. Heidenhain points out the futility of any view which considers the lymph to be merely a sort of branch of the blood stream bringing the nourishing materials nearer to the tissues. The amount of lymph which passes through the thoracic duct of a resting dog of 10 kilos in twenty-four hours, appears to be from 500 c.c.m. to 650 c.c.m. Movement unquestionably increases this amount, but it is uncertain to what extent, probably, however, usually much less than has been inferred from forced movements which appear to about triple the flow. The amount of lymph which must flow in order that its proteids (4.0%) should supply the requirements of the body, according to Voit, is at least ten times as much. Equally striking are the results of a comparison of the amount of lymph needed to supply the mammary glands of a good cow. The lymph of the thoracic duct is *not*, then, the real tissue lymph, but is merely what is drained off as superfluous material, so to speak, from the lymph spaces when the pressure there has risen to a certain height, and the lymph stream is no exact measure either in its quantity or its quality of the processes going on in the lymph spaces of the various organs. Heidenhain believes that no filtration hypothesis can explain this and the results of his experiments; there is some form of cell activity—a "secretion"—in play.

The influence of changes in arterial or venous pressure had been studied by others, but only on the extremities, and the results favored the filtration theory. Heidenhain examined the effect of changed blood pressure upon the flow from the thoracic duct, and comes to quite other conclusions. Lowering the arterial pressure, through closure of the aorta by means of a rubber-bag filled with water, does not stop the flow of lymph; it goes on for a couple of hours at least. The amount may diminish somewhat, but usually not at all, and the variation stands in no relation to the arterial pressure. Such lymph contains somewhat more solids, but this is not due to any slowing of the lymph stream, and is also less coagulable. Closure of the portal vein caused a rapid increase in the lymph stream, but the amount of solids was much smaller—as Emminghaus had also shown. When the arterial pressure was also much reduced, the same result was reached, but the lymph was at first more concentrated. Closure of the vena cava above the diaphragm, which also of course must lower the arterial blood pressure rapidly, and

¹ The object of the "notes" is not merely to report some things that are new, but also to make more generally known some work that, while not absolutely fresh, has not received the general attention that it deserves.

² R. Heidenhain: *Versuche und Fragen zur Lehre von der Lymphbildung*. *Pflüger's Archiv*, xlii, 209.

greatly increases the lymph flow, and this lymph is much richer in proteid material. In both forms of venous stasis the coagulability of the lymph is greatly lessened. Obturation of the portal vein produces marked hyperæmia of the intestines; but closure of the vena cava causes anæmia of the intestines and hyperæmia of the liver, on account of the lessened inflow of blood due to reduced arterial pressure and of the valves of the veins which prevent the blood, driven inward to the liver, from returning to the intestinal vessels.

It is evident that these are conditions which are not at all in accord with a theory of the lymph formation which relies upon filtration to explain the process, although, of course, no one doubts that filtration may take place through such membranes as are here involved, indeed often does take place under pathological conditions. Only the lymph which forms under high arterial pressure when the portal vein is closed may be considered as in a great measure due to filtration, as shown by the presence of many red corpuscles.

Even more indicative of the existence of some cell activity in the lymph formation and of great therapeutic significance is Heidenhain's discovery of the existence of "lymphagogues"—of substances, that is, which increase the lymph flow either by causing a direct "secretion" from the blood, or by withdrawing water from the tissues ("tissue lymph") and sending it into the lymph and into the blood.

The first class of lymphagogues includes most curious material: muscular tissue of crabs (probably *astacus fluviatilis*), heads and bodies of leeches (both *Hirudo medicinalis* and *H. sanguisuga*), the bodies of various mussels, walls of the intestine (dog), "peptones," white of some eggs.

The muscles of crabs, the leeches and mussels may be extracted with boiling water or they may be dehydrated with strong alcohol and the dried powder afterwards extracted by boiling water. The active substance is then not soluble in alcohol and is not destroyed by boiling. Such a decoction may be injected into the blood (dogs and rabbits) without injury. One dog behaved very much as though afflicted with fleas—the substance causing a sort of urticaria. The lymph flow is commonly increased, and this is not due to changes in the blood flow. A quantitative comparison shows that the lymph has gained water and organic substances but not salts, and that the blood plasma has lost water and organic substances. That this transference of material is no filtration is evident from its character and that it is a cell process—a "secretion"—is shown by the fact that when the blood flow has been shut off for sometime the introduction of such lymphagogic substances causes no increase of the lymph flow—the prolonged anæmia having altered the cells whose activity is involved. "Pepton," by which Grüber's "Peptonum depuratum siccum" is meant—probably much proteose and some real peptone—is another lymphagogue. It also alters the blood pressure by modifying the action of heart. The great increase of the lymph flow occurs, however, when the pepton solution goes directly into the aorta reaching the heart only in great dilution, and then causing neither marked change of arterial pressure nor venous stasis. This lymph is also due to the cell action in the walls of capillaries just as in the case of the other substances. Similar results were produced by extracts of some tissues of vertebrates; for example, the wall of the intes-

tine of a dog killed during active digestion, while the experiment was less successful when the animal had fasted for forty-eight hours. Moderate effects were obtained with extracts of dog liver and ox pancreas, slight with lymph glands of the dog, and none with muscles of the pike and rabbits, or with the spleen or dry blood of dogs. In some instances a dilute solution of the white of egg had a very marked lymphagogic action, but the active substance is not present in every egg.

There is a second class of lymphagogues which increases the lymph flow by taking substances from the other tissues and not from the blood. To this group belong sugar, urea and salts when sent into the blood in considerable quantities. Such substances leave the blood rapidly (as others had shown) and the blood gains water. But the introduction of sugar (grape sugar) or sodium chloride also enormously increases the amount of lymph and at the same time the flow of urine from the kidney. Since the amount of water in the blood, in the lymph, and in the urine becomes greater it follows that this "sugar lymph" can have no other source than the water of the tissues—it is tissue lymph and not blood lymph. The amount of salt necessary to produce such a result is much smaller than that of the sugar. The lymph stream will grow to five or six times its original amount by the introduction of 0.6–0.8 gm. NaCl for each kilogramme of body weight while 3.0–5.0 gm. of grape sugar per kilogramme would be needed. Heidenhain made a few comparative experiments and found that the lymph flow varies according to the power of the various salts used to draw water from the tissues.

The difference in the action of these two groups of lymphagogues is made clear by the fact, that, when the aorta has been nearly closed for a couple of hours and the introduction of the various extracts already mentioned causes no increase of lymph flow, it increases at once upon the introduction of sugar or salt. The "sugar lymph" is, then, not directly dependent upon the activity of the cells of the capillaries, or, rather, not so directly as that produced by the other lymphagogues. The passage of the sugar into the lymph cannot be explained by any simple diffusion, for it goes on at a time when the lymph contains much more than the blood. The cell wall of the capillaries must be thought as transferring the sugar to the lymph spaces where the attraction for the water manifests itself, and thus the lymph flow increases. Probably the behavior of the salts is the same, but this is not so easily determined.

The way in which the water of the blood is increased is also not clear, nor is it easy to form a distinct idea of the way in which the kidney secretion is influenced. Perhaps the substances under consideration are secreted in a concentrated form in the cortex and take up more water from lymph channels and blood capillaries while passing down through the loops and other parts of the tubules. It must be distinctly borne in mind that the lymphagogues of the first class do not act upon the kidney.

The great significance of these results, incomplete as the experiments are, is evident upon the briefest reflection. The action of many saline waters is perhaps due to some such movement of the lymph, which may be thought to purge and purify the tissues without the ordinary purging action of the salts being an important feature at all. Possibly other drugs (with an

"absorptive" or "derivative" action) may be supposed to work in some similar way. May it not be that the damage done by diabetes mellitus is explainable in this way, the presence of much sugar in the blood causing the formation of abnormally much lymph (tissue lymph) to the detriment and weakening of the tissues? The hope, too, is awakened that other "lymphagogues" may be found whose action can be applied to benefit the tissues by causing them to obtain a richer lymph and in larger quantities than they have been receiving and thus improving their nutrition. The entire subject is tremendously suggestive.

THE QUESTION OF NERVE FATIGUE.

Some years ago it was shown, but rather inconclusively, by Bernstein, that tetanic stimulation of a motor nerve in frogs caused no fatigue since the muscles would still twitch when the current which had been interposed to block the stimulation was removed. An improved demonstration of this fact was made several years later by Wedenski. It was then shown by Bowditch⁸ that the use of curare made it possible to demonstrate that the behavior of the nerves in warm-blooded animals (cats) is the same. The motor nerves do not fatig. The same author⁴ afterwards published a still more complete demonstration by experiments upon dogs. A motor nerve may be tetanized for hours and yet as the curare used to check movement and fatigue of the muscles loses its effect, that is, is eliminated, the muscle fibres are again led to contract, the stimulation still passing down the nerve apparently in undiminished vigor.

It is, of course, important to inquire whether a similar immunity to fatigue exists in other nerves. For the sensory nerves (Langendorff) it is rendered very probable by the persistence of pain, as in toothache, which may be as great upon awaking as when we went to sleep, but a different form of demonstration is very desirable. Szana⁶ has made some experiments which show that the inhibitory fibres of the vagus (at least in the rabbit) are not fatigued by long-continued stimulation. By using atropine the inhibition of the heart-beat could be prevented, although the vagus was tetanized for hours; but as the atropin effect wore off (elimination), the inhibitory action of the nerve became apparent and gradually regained its full power.

RECENT WORK WITH ALCOHOL.

In reviewing the evidence concerning the physiological action of alcohol one is much impressed by the very unsatisfactory character of the experiments made to determine the effect upon the nitrogenous metabolism. Chittenden⁸ has recently reported a small series of observations made with great care upon dogs, and which may be greeted as a most acceptable addition to our knowledge of the subject. The animals were fed upon a diet of dried meat and milk crackers, whose nitrogen could be exactly determined, and they appear to have been in nitrogenous equilibrium. In each of the three experiments there was a period of some days without alcohol at the beginning and again at the end, the middle series of eight to ten days forming an

⁸ R. H. Chittenden (with Norris & Smith): The influence of alcohol on protein metabolism. *Journal of Physiology*, xii, 220.

alcohol period during which the dog received average amounts of 1.9–2.7 c.c.m. of absolute alcohol for each kilogramme of body weight.

Such experiments would be expected to give very definite results if alcohol have a very pronounced influence on the metabolism. They show that "no very striking specific action upon the general metabolism of protein matter" is caused by such amounts given to dogs. Chittenden thinks that the alcohol must be considered as acting as a non-nitrogenous food, and that the nitrogen of the body may be protected and the nitrogenous output somewhat lessened. Two of his series do show such a diminution of the nitrogen in the excreta during the alcohol period. In both of these cases the day which followed the cutting off of the alcohol-supply showed a great increase in the nitrogen output, as though, Chittenden thinks, some check had been removed from the metabolism of the proteins. A vigorous enemy of alcohol would probably argue that "effete material" had been retained, but he would find it hard to explain why so little effect is produced if alcohol be as harmful as is usually maintained. One very suggestive point is brought out in these experiments by the observation that the excretion of uric acid is much increased (in one series it was doubled) by the action of the alcohol. Whether this be due to freer excretion or to increased production is not clear, but the point seems worthy of further examination, and may throw light upon the relation of alcohol to the "uric acid diathesis." In these experiments no distinct diuretic action was observed.

Another contribution to our knowledge of the physiological action of alcohol has been made by Strassmann.⁷ He fed young dogs of the same litter liberally and regularly, giving some of them measured quantities of pure or impure spirits. These experiments lasted about seven weeks, when the animals were killed and weighed. As the animals were young (only about two months old), the number rather too small for comparison, and the quantities of alcohol decidedly large, it does not seem prudent to make many inferences from the figures reported. The percentage weight was distinctly greater in the alcohol dogs for liver and kidneys (muscles and bones not noted), but especially for the fat which was more than doubled. This line of work deserves to be followed up with great care.

In other experiments, upon man, Strassmann endeavored to determine more accurately the elimination of alcohol by the lungs, not feeling quite satisfied with the method employed by Bodländer who had found that the lungs carried off about 1.6% of the alcohol in dogs while man loses 1.2% in this way. The respiration apparatus of Zuntz was used, with the modification that a flask was attached, the air of which was considered to be a fair sample after the expired air had passed through the apparatus for half an hour, and the amount noted. The alcohol vapor in the flask (containing some 1750 c.c.m.) was estimated by the chromic-acid method, and the amount calculated for the hour. In this way six experiments were made on three persons, as against Bodländer's three experiments on himself, but with quantities which may be considered to be fairly comparable with those employed by Bodländer. The average amount excreted by the lungs during four hours, after which time the excretion lungs during four hours, after which time the excretion

⁷ Strassmann: Untersuchungen über den Nahrwerte und die Ausscheidung des Alcohol. *Phüger's Archiv*, xix, 1891, 315.

is insignificant, was 5.1% of the quantity of alcohol taken—decidedly more than the 2.0% regained by Bodländer in his expired air. The examination of the urine made by Strassmann in five experiments on two persons determined an average output of 1.7% of the alcohol through the kidney in man, Bodländer's figures being 1.2%; but as the average in one of Strassmann's men is 1.35%, renal peculiarities may be in play. Strassmann agrees with Bodländer that there can be no doubt that by far the greater part of the alcohol is disposed of in the body and not excreted as alcohol; but he thinks that his determination of the amount lost by the lungs and kidneys is more exact, and justifies the conclusion that as much as 10% may be lost leaving 90% to be made use of in the body presumably as a "force producer."

It is perhaps worth while to call attention to one point in this investigation, while admitting that the method is in principle an improvement upon that of Bodländer. Strassmann seems to have made but one control experiment to test his method and he then recovered only 89% of the alcohol which had evaporated from his mixture. Since the method itself multiplies any error in the determination by about 250, and since the determination depends upon color comparisons, it is hard to say how much exactness may be credited to the observations. It may also be fairly urged that the respiratory movements, while not affecting the oxygen and carbon dioxide whose proportions are dependent upon the tissue respiration, are sufficiently altered to render the excretion of the alcohol by the lungs greater than it would be normally. Some of the irregularities in Strassmann's tables strongly suggest this and one experiment with forced respiratory movements, by which the exhalation of the alcohol seems to have been markedly increased, although not conclusive, points in the same direction.

In another series of experiments made in the same laboratory¹ the influence of alcohol upon the digestion was incidentally examined. It was found that 60 gm. of alcohol had no deleterious influence upon the digestive powers of a man accustomed to take that quantity, as compared with the digestion of a similar diet in another man using no alcohol.

(To be continued.)

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

J. C. MUNRO, M.D., SECRETARY.

REGULAR Meeting Monday, December 7, 1891,
DR. CHAS. B. PORTER in the chair.

DR. W. F. WHITNEY read a paper on

FAT EMBOLISM.²

DR. A. T. CABOT: I remember very well the first case that brought the subject of embolism to my mind. The case was that of a man with fractured thigh. Very severe dyspnoea came on, and he died on the third or fourth day. I, myself, made the sections of the lungs, and found them very generally filled with fat,

¹ See page 139 of the Journal.

² Zuntz and Magnus-Levy: Beiträge zur Kenntniss der Verdauungskrankheit und des Nährwertes des Brodes. Pflüger's Archiv, xlii, 438.

that is, the capillaries. It was a fat leg I remember, and it seemed at that time as if the symptoms were largely of the respiratory system, and were, we thought, adequately accounted for by the amount of fat found in the capillaries of the lungs.

In regard to the case Dr. Richardson speaks of, at the time I saw it my reason for not advising operation was that I did not think the man would survive the operation. I should like to ask Dr. Richardson if he has figured out any lesions that he would be likely to find.

DR. M. H. RICHARDSON: I must have expressed myself badly, for I meant to say the diagnosis was extremely obscure, and that it was very doubtful whether operative interference would do any good whatever, though it seemed possible that some removable cause might be found. The first twelve hours the symptoms did not seem serious enough to justify operation, and during the next twelve the patient suddenly became so much worse that operation was out of the question.

DR. CABOT: It seems to me, in cases where the lesion is occasioned by a fall which sets up a peritonitis, you almost always have some symptoms of that lesion earlier in the history of the case, immediately after the case comes under observation you have some symptoms of pain and local tenderness. It seems to me with those symptoms an immediate laparotomy might be advisable. I have not many data to go upon, but I should hardly think with the absence of those symptoms a laparotomy was likely to show a lesion that could be remedied.

DR. CHARLES P. PUTNAM: I should like to ask if Dr. Whitney gave any theory as to the cause of the condition of the contents of the stomach and upper part of the intestine in the case of the man.

DR. W. F. WHITNEY: The stomach presented a few small haemorrhagic erosions, such as are apt to occur in cases of severe and prolonged vomiting, and apparently there had been no peristaltic movement to move the dark-colored contents of the intestine along. It is possible that both of these cases of intestinal disturbance may have been, as I suggested, of central origin and due to fat embolism of the brain. Certainly, in the case of the man, there were no appearances of peritonitis found at the autopsy. There was a distension of the intestines from the stomach to the rectum, but beyond that there was absolutely nothing beyond slight injection of the surface not inflammatory in character nor accompanied by any exudation. The similarity in the symptoms of these two cases is very marked, and the fall in temperature in both was very striking. This was one of the most constant symptoms noticed in cases of fat embolism, and as in both of these it occurred at the time when most of the recorded cases die, it is fair to suppose that it may have been due to such embolism.

As regards what Dr. Cabot said, of course there is always the objection that we cannot with absolute certainty take the results of experiments on animals and transfer them without any further consideration to man. In animals we find that a very large amount of the pulmonary circulation must be shut off before rise in arterial tension is found, but I do not think we can say a less quantity may not produce very grave symptoms in man.

I would like to ask Dr. Richardson or Dr. Cabot if it is customary to see as much rise of temperature after ordinary cases of simple fracture as found in these.

DR. CABOT: Fracture of what bone is particularly liable to be followed by this?

DR. WHITNEY: I think it depends a good deal on the laceration of the tissues besides that of the bone-marrow itself. Fat embolism has been found after almost every fracture that has been known. In one case I found it in the kidneys three-quarters of an hour after a case of simple fracture of the skull. It has been found in a number of cases of puerperal eclampsia, but the origin of the fat was very doubtful. In cases of rupture of the liver and absorption of fat from the peritoneal cavity, emboli have been found. In insane people who have thrown themselves against the side of the room and received severe contusion, embolism has resulted. In these cases there is a comminution of the subcutaneous fat tissue from which absorption can take place as well as from the bone marrow. It has been noticed after the removal of fat tumors and resection of the knee-joint.

It seems to me that really the cases in which death can be attributed solely to the fat are very few, and that it is usually complicated by a septic process.

DR. H. F. VICKERY: May I ask whether fat cannot go through ordinary capillaries perfectly well, whether that is not one argument that it must be in the brain's terminal arteries alone that fat can do harm?

DR. WHITNEY: I think it must go through the ordinary capillaries, but why it should remain stored up for a week and then appear again is a very curious point.

DR. RICHARDSON: We are much indebted to Dr. Whitney for his valuable communication upon this important subject, for it shows us that we are liable to make grave mistakes in the treatment of fractures of long bones if we do not bear in mind the possibility of fat embolism, and may subject patients to unnecessary risk and suffering by useless operative interference.

In reply to Dr. Cabot I would say that in both my cases we had just that combination of symptoms which, in the absence of traumatism at least, demands immediate exploration of the abdomen. This was especially true of the first case reported. The symptoms seemed to indicate either an acute obstruction or a general peritonitis, or both. I do not think anybody suspected in either case the presence of fat embolism.

The importance of this pathological condition and the symptoms by which it manifests itself have been strongly impressed upon me by Dr. Whitney's paper, and I hope to profit much by his recommendations.

DR. C. B. PORTER: I agree most cordially with what Dr. Richardson has said as to the debt we shall owe in the future to Dr. Whitney's paper to-night. I can recall but one case, as I run back in my mind over the fractures with sudden death, and that is of one in recent years. I do not remember the exact facts about it, but I think it was fracture of the leg. The autopsy proved it to be a case of fat embolism. I think there were no abdominal symptoms, but respiratory and cerebral symptoms.

DISCUSSION ON INTERNAL ANTISEPSIS.

DR. H. C. ERNST opened the discussion.²

DR. F. H. WILLIAMS: The subject seems to me of much importance, and I think that by careful treatment we can do something in the direction of intestinal antiseptics both from a dietetic standpoint and also by the administration of suitable remedies. It is obviously desirable that the remedies should not dissolve

in the stomach, and also it is important that they should not be poisonous. Calomel which has been much used is not very soluble. Salol is given by many practitioners, but it has some dangers; by its decomposition carbolic acid is formed, which may be absorbed by the system and, as a matter of fact, cases have been reported of death with symptoms of carbolic poisoning from the use of salol. I think it is necessary that a warning should be sounded against large doses of salol. Certainly salol ought not to be used except in small quantities, and perhaps there are even better drugs to use. I am inclined to think there are. Hydronaphthol seems to me one of the most promising at present, and I think it may be used successfully, so far as symptoms go, in rather small doses. A grain, I think, is a sufficient amount in most cases, to be given as often as once in four hours, and in many cases one-half a grain is a sufficient amount. It is better to give these remedies between meals, so that they may not interfere with digestion.

As regards what the patient shall eat, I think much care can be exercised to advantage. Last summer at the City Hospital I used what is known as evaporated milk, that is, milk prepared by putting fresh milk into a vacuum pan and concentrating it so that it is four times as strong as ordinary milk. It can then be transported and kept fresh a considerable time, a week or ten days. When that kind of milk is diluted at the bedside it seems to me the patient is likely to get something which may be serviceable. Certainly this last summer the typhoid fever cases did seem to me to do better, so far as abdominal symptoms are concerned with treatment on evaporated milk, with small doses of hydronaphthol. I hope that in the near future we shall be able to do much towards intestinal antiseptics, and that we may have tests of the urine which will show us how well we have succeeded in our efforts.

DR. J. A. JEFFRIES said he was very glad to learn that efforts were being made in the City Hospital to provide typhoid patients with relatively sterilized food. Some years ago when studying the summer diarrhoea of infancy he had tried to impress upon the profession the importance of this measure, not only for children but also for adults.

Turning to the subject of intestinal antiseptics, that is, the killing of bacteria in the intestines, he did not think that any of the drugs now known were successful. The highly complex mammalian organism is more susceptible to poisons than the bacteria, and at the present time we could not poison the latter without injury to the former. The satisfactory course of a disease under the administration of an "intestinal antiseptic" did not show that the bacteria were in any way affected. This could only be demonstrated by examination of the bacteria in the stools, and such examinations did not give satisfactory results. When diarrhoea had been set up and the volume of the dejecta was increased, there was a relative diminution of the bacteria at times, and but little more. This was a mechanical action equal to the washing of a wound, and to be more safely accomplished, where indicated, by a cathartic. Any one who had experimented upon animals and had seen the results at times induced by non-fatal and inactive doses — so far as bacteria are concerned — would be slow to take them himself.

Some of the gentlemen have referred to the want of some other measure of the patrefactive changes going on in the intestine. We have had such for years.

² See page 157 of the Journal.

Certain of the products of bacterial growth — sulphuric ethers and aromatic compounds — are absorbed by the intestines and eliminated by the kidneys, as pointed out by Marox, Baumann and others.

Calomel, iodoform and a few other drugs of more or less use seem to act on the intestines not by killing the germs but by combining with the poisons and rendering them inert, the same as tannic acid and some of the alkaloids. A consideration of the bacteria in the liver and spleen in typhoid, phagocytosis immunity and the like are far from the question under discussion — intestinal antisepsis.

DR. H. F. VICKERY: An attempt at internal antisepsis is one that we ought to make, and I believe that some generation of physicians will succeed. There is one difficulty about it that has not been dwelt on. To realize internal antisepsis you have got to follow these micro-organisms around. They are not merely in the intestine. For instance, the bacillus of typhoid fever is found in the spleen also, and I do not think it is proved that all the harm that the typhoid bacillus does is transacted in the intestine. The preparing of the individual to carry on his natural fight against the disease-causing organisms is a rational measure, as has been mentioned, the giving him all the strength we can; and it also is a rational measure to keep the contents of the bowel moving on, within proper limits, as has been suggested by the last speaker. But it does seem to me at this present stage that asepsis bears the same relation to antisepsis internally as asepsis in performing a laparotomy does to an endeavor to cure a person with general septic peritonitis. We must try to have the air breathed, the food and drink swallowed, harmless. That is the most important service we can possibly accomplish. It is by what is called public medicine, hygiene, we can do the most good in this line.

DR. C. B. PORTER showed a

DERMOID CYST,

removed from a young woman twenty-six years of age. Her catamenia began at fifteen, and there was nothing remarkable in connection with them. She has had six children, and been married seven years. Five months ago she had twins. She has had pain in the back two years, and vaginal discharge three years. Only three months before the tumor was removed did she notice its presence. She was not able to lie on the left side since on account of pain. The tumor, as it presented itself through the abdomen, was considerably larger than a two-quart jar, and movable, and was very rapidly reached by the ordinary incision by laparotomy. Upon introduction of the trocar there was no excretion of the fluid at all, although it was evident it was a fluctuating tumor; and after ineffectual attempts and stripping the rubber-tube, it was found we could not get any fluid in that way, and upon withdrawing the trocar a fatty fluid flowed out and the tube was plugged by this mass of hair. I was finally obliged to turn the woman on the side, and allow the contents to flow out before I could introduce the hand and get the tumor out. The operation was done two weeks ago. The patient is now well.

Dr. Porter also showed

FOUR CALCULI REMOVED FROM THE BLADDER BY SUPRAPUBIC SECTION.

The patient was a man eighty years of age, and had

had difficulty in micturition for five years, and had been obliged to use the catheter the whole of that time. He had been troubled to a very considerable extent with haematuria, and his attending physician at one time in the passage of the catheter thought he felt a grating in the bladder. The operation was done November 21st, and upon exploration of the bladder, both previous to the operation and at the time of the operation, it was impossible to strike the stone. One could get with the sound a sensation of grating. I opened the bladder by the suprapubic section and removed the four stones. One is quite small. The urethra was surrounded entirely by an enlargement which made it simulate exactly quite a good-sized os uteri with quite hard and prominent mouth and lips, and these I seized with forceps and cut off with curved scissors. The tubes are out from the suprapubic wound and he is passing most of his urine through the catheter that is placed in the bladder, and a little oozes out still from the wound. He is doing remarkably well, and for a man eighty years of age to undergo such an operation is quite remarkable. I am passing the large sounds, 33 and 34 French, every third or fourth day into the bladder, in the hopes of so moulding what is left from the prostate, that if he recovers from his ventral wound he will be able to pass his water in the natural manner.

Recent Literature.

A Text-Book of Physiology. By M. FOSTER, M.A., M.D., F.R.S., Professor of Physiology in the University of Cambridge, and Fellow of Trinity College, Cambridge. Fourth American from the Fifth English Edition, thoroughly Revised, with Notes, Additions and 282 Illustrations. 8vo, pp. 1072. Philadelphia : Lea Bros. & Co. 1891.

At first glance the book may seem to be a faithful reprint of the last (fifth) English edition, but unfortunately this is true of only part of it. As far as, and including page 886, the volume before us seems to be a fairly accurate reprint of Parts I, II and III of the fifth English edition, containing but few typographical errors, and no important additions to the text. About seventy-eight figures have been inserted, but few of which are, however, strictly physiological in character most of them being illustrative of anatomical structure. The remainder of the book, that is, from page 887 to the index, including both, seems to be simply a reprint of the corresponding portion of the third American, and in no way represents Part IV of the fifth English edition to which, according to the title-page, it should correspond. This oversight — if such it be — is very unfortunate, inasmuch as it impairs greatly the value of the book, and as a reference book to the many students now possessing a copy, who may be unaware of the defect, renders it — this portion at least — worse than useless.

The fifth English edition of Part IV differs greatly from the fourth, though two of its chapters are practically the same as the corresponding chapters in the fourth edition.

The Appendix, by Mr. Lea, "On the Chemical Basis of the Animal Body," has not so far as we know appeared in a revised form since the publication of the

fourth English edition (1883), though it is forthcoming, and will form a companion volume to the last English edition. There is one typographical error to which it would seem proper to call attention. On page 54 the words "give out something" have been omitted after "taken place" (line 7). This omission renders the sentence to which the words belong quite unintelligible.

The name of the American editor does not appear.
J. C. C.

An Introduction to Human Physiology. By AUGUSTUS D. WALLER, M.D. Lecturer on Physiology at St. Mary's Hospital Medical School, London; Late External Examiner at the Victoria University. 8vo, pp. 612. London: Longmans, Green & Co. 1891.

The author's style is peculiarly clear and simple, and his language exact. Part I deals with "The Phenomena of Nutrition," under which heading are discussed the physiology of the blood, circulation, respiration, digestion, secretion, excretion, metabolism and animal heat. Part II deals with "The Phenomena of Excitation," under which heading the author includes the physiology of the neuro-muscular system and of the sense organs.

The Appendix contains a section summarizing the knowledge thus far accumulated relative to the physiology of the embryo, and a chapter giving the "Constitutional Formulae of some of the Chief Proximate Principles," which latter we hope will be of great use to the student in aiding him in his endeavor to form a "living mental picture of what the great organs below a man's skin are like, what they are doing, etc.," of which the author states in the preface physiology "should fundamentally consist."

A brief and quite well chosen Bibliography has been appended in the hope of affording the student a "few main starting points and indications."

At the head of each chapter is a syllabus of its contents, in which by means of a prefixed asterisk those sections which treat more especially of the details of the subject are indicated.

It is well calculated as a text-book for junior students of medicine for whom it seems to have been primarily intended, while it contains able discussions of some of the yet unsettled questions which will make it of value to more advanced students. The descriptions of methods and of apparatus are very clear and precise, facts are well stated and conclusions neatly drawn.

There is a place for it among English text-books of physiology which is at present filled by no other.

J. C. C.

Physical Diagnosis. A Guide to Methods of Clinical Investigation. By G. A. GIBSON, M.D., D.Sc., F.R.C.P., Ed., and WILLIAM RUSSELL, M.D., F.R.C.P., Ed. With one hundred and one illustrations. New York: D. Appleton & Co. 1891.

This is a small octavo of 367 pages. The authors are both teachers in the Edinburgh Medical School, and one of them is also connected with the Glasgow School. The book, as its title implies, is a hand-book for students, and is limited entirely to the consideration of physical examination.

It is a convenient and, our examination indicates, a reliable compend for the purposes for which it was prepared.

THE BOSTON Medical and Surgical Journal.

THURSDAY, FEBRUARY 18, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

TYPHUS FEVER IN NEW YORK.

THE most serious outbreak of typhus fever that has occurred in the country for many years, became known to the health authorities of New York late on the night of February 11th, and on the following day no less than fifty-eight cases of the disease were discovered. The history of the rise and spread of the typhus is as follows: On January 30th the French steamer *Massilia*, of the Fabre line, arrived with 717 steerage passengers. Two hundred and fifty of these were Russian Hebrew immigrants who were aided by funds provided by Baron Hirsch, and they were first transported from Odessa to Constantinople, whence they hoped to be able to go to Palestine and settle. Being disappointed in this, through the action of the Turkish authorities, they came to Marseilles, where they embarked on the *Massilia*, together with a considerable number of other immigrants of various nationalities. The steamer on January 1st, took on board more than 200 Italians, and on January 12th she sailed from Gibraltar. During the voyage to New York, according to the passengers' accounts when they landed, they were insufficiently fed, and four died in mid-ocean. On the ship's arrival eleven passengers were still ill, three of them with what was believed to be typhoid fever, but which, as the sequel shows, was undoubtedly typhus. They were all sent to the immigrant station on Ellis Island, the Russian refugees unfortunately being permitted to land on the understanding that the United Hebrew Charities, which have charge of the disposition of the Baron Hirsch fund in New York, should not permit them to become a burden in this country! They were for the most part in a pitiable state of destitution, and some \$400 was expended in providing clothing for them.

One of the houses to which they were sent was on 12th Street, near Third Avenue, and a number of its inmates were soon reported ill. A physician in the service of the United Hebrew Charities, was called to attend them on February 8th, and learning that there had been cases of typhoid fever on the *Massilia*, he made a diagnosis of that disease. On the evening of Febr-

ary 11th, he became so alarmed at the gravity of the outbreak, that he sent word to the Bureau of Contagious Diseases to remove some of the patients to the hospital. At 11 o'clock that night Dr. Roberts, an inspector of the Bureau, made a visit to the premises, and early the next morning Dr. Cyrus Edson, chief of the Bureau, went there to investigate, when to their astonishment, these officers found fifteen well-developed cases of typhus, and it was ascertained that the first case had occurred on February 2d. These fifteen cases, together with the mothers of four of the patients who were young children, were at once sent to the hospital on North Brothers' Island, and the most prompt and thorough measures of disinfection taken in the house.

A search was then made at the other tenement-houses where the Russian refugees had been lodged, and this resulted in the discovery of forty-three more cases of typhus, which were all sent to the hospital for contagious diseases. It was ascertained at the same time that about sixty of the Russians who came over on the *Massilia* had already been sent to situations in different parts of the country, so that they will be likely to take the disease with them.

On the day following, February 12th, eleven additional cases were discovered among the Russians. Every effort was made to trace the Italian and other immigrants who came on the *Massilia*, but it was found that many of them had left the city. A special meeting of the Board of Health was also held, and resolutions were adopted, taking suitable measures to prevent the dangers of infection from the immigrants from the steamer *Massilia*, and to provide hospital accommodation for the cases as soon as discovered. On February 13th, five additional cases of typhus were found among the Russians from the *Massilia*; February 15th, seven more cases; February 16th, six cases at Oakdale, Mass.; and each day is adding to the list. There are, at time of writing, eighty-nine cases at North Brothers' Island.

The whole country is more or less alarmed and disturbed, and really in a certain measure endangered by the living freight which this steamer has been allowed to land upon our shores after it had been refused the hospitality of the intelligent Turk.

We have thought it worth while to put together the main facts in the case as an illustration of the daily folly which we as a nation are permitting to be committed in the beautiful name of freedom, to the relief of other countries, the profit of a lot of steamship companies, the gradual degradation of our population, and the positive diminution in the safeguards for life, liberty and the pursuit of happiness which those already living here would like to be assured of. We open our doors to squalor and filth and misery — which mean typhus fever, and we admit leprosy almost as if these things were blessings in disguise.

The reports of the Treasury Department show that for the last six months of 1891, the number of immigrants coming from Russia (Poland excepted) in those

months was 46,710, as against 20,934 in the corresponding months of 1890. The whole number of immigrants was greater in 1891 than in 1890 by about 100,000, and nearly half of this increase is ascribed in the reports to Russia and Poland.

As sanitarians, with this text before our eyes, we desire to add our indignant protest to that expressed by the eminent statistician, Gen. Francis A. Walker, in a recent lecture against the results of our immigration laws. There are times when charity should begin at home.

SUICIDE IN THE EUROPEAN ARMIES.

THE percentage of suicides had become so great in the French army that the French Minister of War sent Dr. Longuet as a special delegate to the International Congress, held last summer in London, to communicate the results of his studies relative to suicides in the armies of Europe. Mr. F. P. Emery summarizes these results as follows:¹

The Austrian army leads, with yearly average of 122 suicides for every 100,000 men in the effective troops, for the years 1875 to 1887, inclusive. The maximum was observed in 1889, when it was 149 per 100,000; the minimum was in 1878, when it was 97. In this army suicide is appreciably increasing; death by suicide represents a fifth part of its entire mortality; there is no disease that is more prominent in the list of causes of death.

The German army ranks next to the Austrian in this connection. The ratio of suicides here during the years 1878 to 1888 was 67 per 100,000 annually. Here, also, suicide is on the increase.

In the Italian army, from 1874 to 1889, there were 40 suicides per annum per 100,000 troops. In contrast with what is above stated as to the increase in this army mortality in other countries, the army mortality in Italy due to suicide, has remained nearly stationary during a series of years.

In the French army (home service) there were in each year from 1872 to 1889, an annual average of 29 suicides per 100,000; in Algeria, the French soldiers killed themselves during the same period at the rate of 63 per 100,000.

In the Belgian army the suicide rate was 24 to every 100,000.

In the English army (home service), from 1882 to 1888, the rate was 23 per 100,000; in the Indian service (Bengal division) it was 48.

In the Russian army the rate from 1873 to 1889 was 20, with a maximum of 91 in 1882.

The Spanish army, at the foot of the list, but for a single year only (1886) gave a rate of 14 suicides per 100,000 men.

In the old armies, especially those recruited by enrolment, it was the older soldiers who generally committed suicide. This is still actually the case in the English army. In France, Italy, Germany and Austria, on

¹ Publications of American Statistical Association, Sept., 1891.

the other hand, it is to-day the young, rather than the old soldiers, who commit suicide. In Austria there is an excessive proportion of suicides of young soldiers, who kill themselves during the first month of their service. The under-officers present three times the proportion of suicides that are found among the troops; while the officers, who are older men of higher rank, furnish twice the number. It is among the engineers that the suicides are generally least frequent; among the cavalry and infantry the most. Condemned soldiers in the military prisons and penitentiary institutions rarely take their own life. On the contrary, there are frequent suicides in the corps prisons, among those soldiers who are accused and are awaiting trial.

Shooting is the most frequent method. It counts for more than one-half, and in the Austrian army for three-quarters, of the whole number. This proportion is four times as large as that offered by the civil population. Hanging and drowning are the two other modes that are most frequent. It is worth while to note that in the English army there is a great frequency of suicide by cutting the throat, a mode of self-murder unknown in the French army, but which occurs to a slight extent in the German.

It is in the infantry that the use of fire-arms is most common. Among the mounted soldiers hanging is much more frequent, and is often accomplished by means of the horse-brides. In the prisons, hanging is the almost exclusive mode.

Those who shoot themselves almost universally aim at their heads. The army in Algeria, however, forms an exception. With these soldiers it is almost always the body that is shot; usually the abdomen or the chest; sometimes the neck, the shoulder, an arm or a leg. May this not be due to the fact that among the Arabs an idea of infamy attaches to the mutilation of the head?

The seasons exercise their influence upon the manner of suicide; and in summer drowning is much more frequent.

In the Austrian army a third of the suicides are attributed to a distaste for military duty. This cause shows itself with much less frequency in the other armies. The fear of punishment is said to cause one in three in Austria and Germany, one in five in France, and one in seven in Italy. Suicide caused by some love trouble is much more frequent in France, where one-fifth of the whole number is attributed to this cause, and in Italy, where it is responsible for one-seventh, than in England, Germany and Austria. Mental disorders represent from one-fifth to one-twelfth of the whole number.

The increase in the frequency of suicide during the hot season is as marked in the army as among the civil population. The maximum suicidal mortality is reached during the hottest summer months, and the minimum during the coldest of the winter.

THE State Board of Health of Kentucky, have begun a vigorous prosecution of quacks and travelling doctors in Louisville.

HYGIENIC LEGISLATION.

OUR legislative committees have to listen sometimes to very funny petitions. The Committee on Public Health of the Massachusetts Legislature has recently been hearing arguments on the petition of the Woman's Christian Temperance Union, asking that all boys under sixteen years of age found smoking in public places be arrested, locked up, taken into court and fined. The petitioners complained that the present law prohibiting the sale of tobacco to minors was not enforced; but they seemed to think that by arresting boys *flagrante delicto*, the youth of the State would be frightened into abstinence. This, surely, shows a great lack of knowledge of the character of the small boy. If by such a simple expedient as smoking a cigarette he could make his natural enemy, the policeman, take an active part in a game of hare and hounds, the supply of cigarettes would soon fall far short of the demand.

One of the more enthusiastic of the petitioners informed the committee that tobacco is a deadly poison, and related several cases within her experience in which cigarettes had ruined boys of her acquaintance. If her boy smoked, she would rather have him arrested than not, and she should prefer that he be kept in jail until he was seventy years of age rather than have him become a confirmed smoker.

We do not wish to imply that it is not very desirable to prevent minors from smoking, if possible, but there are several similar bad habits which are freely indulged in, and which do much more harm than juvenile smoking. We respectfully suggest that if this bill is to be acted on, there be included in it a section making it a misdemeanor to feed a child of less than three years of age on seed-cakes, pickles, candy or tea. If this provision were carried out many, possibly valuable, lives would be saved to the community every year. Also, as there is no reason why hygienic legislation should be limited by age, much more suffering than is caused by cigarette smoking, both to the victims and their friends, would be saved by arresting all women who drink more than a pint of tea in the twenty-four hours.

Several similar amendments to the bill suggest themselves, but some of them would be difficult to enforce, and it is of great importance to the public that the duties of the policeman should not be made greater than is consistent with the limitations of time and strength.

MEDICAL NOTES.

PAN-AMERICAN MEDICAL CONGRESS IN NEW YORK STATE.—At a meeting of the Medical Society of the State of New York at Albany, February 5th, a committee was appointed to co-operate in promoting the interests of the Pan-American Medical Congress. The committee consisted of Drs. A. Walter Suiter, A. Van der Veer, James D. Spencer, Seneca D. Powell, W. W. Potter, D. B. St. John Roosa, and John O. Roe.

RUSH MEDICAL COLLEGE. — A Concours will be held at Rush Medical College, Chicago, beginning Tuesday evening, March 1st, for the purpose of filling the position of Lecturer on Anatomy, and on Materia Medica and Therapeutics in the spring Faculty. The spring course begins March 31st, directly after the close of the regular term, and continues two months with a class of from 250 to 300 students.

THE KHEDIVE'S DEATH. — The *British Medical Journal* has received a series of documents bearing upon the last illness of the late khedive of Egypt. To publish them, it says, or even an analysis of them, would renew the most painful impressions. It is impossible, in the light of all the facts, not to arrive at the conclusion that Tewfik's death was hastened by the untimely administration of morphine. "The whole story is an illustration of the lamentable influence of the harem in bringing about the selection of native physicians, and their control of access to the patient, skill and experience of European physicians being thereby set at naught."

NEW MEDICAL PERIODICALS. — The *Revue Générale de Médecine de Chirurgie et d'Obstétrique*, a weekly journal devoted entirely to short reviews of recent medical papers, appeared for the first time in January. It is published in Paris under the editorial charge of Dr. F. de Rause. The *Hot Springs Medical Journal* has been established in Hot Springs, Arkansas, to appear on the fifteenth of each month. In addition to other subjects, the therapeutic value of the springs will be discussed.

THE LEGAL STATUS OF THE CORSET. — In a recent opinion Judge Wheeler, in the United States Circuit Court, sustains the decision of the Board of Appraisers and of the Collector that a corset is an article of wearing apparel. The decision is as follows: "In this case the question is whether the article known as cotton corsets is properly classified as wearing apparel. In point of fact, it is a waist in which are inserted whalebones or steel for support of the body and clothing. If you were to ask anybody who did not care anything about the matter in any way, but who knew, whether that was an article of wearing apparel or not, or whether a mechanical contrivance, I rather think he would say it was a piece of clothing, that it would help to keep the body warm, and answered the purpose of a waist. I think it is clothing. However, I am not so very confident of it. The finding may be confirmed."

THE BREAD OF THE FAMINE DISTRICTS IN RUSSIA. — The *Lancet* has obtained possession of a specimen of the relief bread furnished by the Russian Government to the starving peasants in the Province of Nizhni-Novgorod, and has had it analyzed. The result shows the addition, in round figures, of not less, and probably more, than ten pounds of foreign substance to every hundred weight of rye flour, including woody fibre and husks, leafy matter and seeds, and containing silica and sand to the extent of more than two per cent. This makes the flour heavier and also increases its bulk. The bread is described as of a dirty

brown color, looking like coarse peat. Many persons to whom it was shown failed to recognize that it was bread at all. A Russian, writing from Nizhni-Novgorod, says: "I found in many cases that this so-called bread contained no rye flour whatever, but was composed of wild arrack, potatoes, chaff and leaves." The daily allowance of this so-called bread judged sufficient to keep the life in a healthy adult is something less than one pound.

BOSTON.

CLOSING OF TENEMENTS. — The City Board of Health have recently ordered vacated a number of tenement-houses, for sanitary reasons.

DEATH-RATE FOR THE WEEK. — There were 194 deaths in Boston last week, making the death-rate 22.1. Of these, nine were due to influenza, three being uncomplicated. The deaths from consumption were 16, pneumonia 27, bronchitis 19. The number of persons over sixty years of age was 46.

MORTALITY OF BOSTON IN JANUARY. — The death-rate of Boston during January was much larger than usual. This was undoubtedly due to the epidemic of influenza — more than appears in the returns. There were 1,190 deaths, as against 894 in 1891, making the death-rate 31.10. Of the deaths last month, 567 were males; 386 were married, 1,160 were white, 285 were under five years of age, 689 were natives of the United States, and 298 were of American parentage. Influenza was reported as the cause of 63 of the deaths; consumption, 150; scarlet fever, 29; diphtheria, 28; bronchitis, 109; heart disease, 84; pneumonia, 240. Scarlet fever was unusually prevalent; there were 290 cases reported against 109 during the corresponding month of 1891.

THE HOME OF THE GOOD SAMARITAN. — The annual report of this institution shows that during the past year 249 patients were treated at the institution, of which 59 were children. The hospital has been much benefited by an entire change in the system of drainage.

THE CHILDREN'S HOSPITAL. — During the year 1891, 603 patients were treated in the hospital, and 1,790 new cases in the out-patient department. The systematic training of nurses has been established, the course to cover two years. The Convalescent Home of the Children's Hospital, a corporation formerly known as the Ladies' Aid Association of the Children's Hospital, reports that thirty-three acres of land were given by Mr. H. H. Hunnewell at Wellesley Hills, and the building is well advanced. The building contains two wards, each holding twenty-three beds, a large play-room, covered piazzas, and other rooms necessary for a well-equipped convalescent home. The managers intend to keep the home open in winter as well as summer, as soon as the resources will allow.

NEW YORK.

A NEW SITE FOR ST. LUKE'S HOSPITAL. — The authorities of St. Luke's Hospital have purchased a

new site for that institution. About \$500,000 was paid for the land, which is 583 by 200 feet, and is situated between Morningside Park and Tenth Avenue, and extends from 113th to 114th Streets. It is quite near the sites selected for the Cathedral of St. John the Divine and the new Columbia College buildings, and the ground has an elevation of 120 feet above tide-water. It is the present design to erect only a section of the building at first. The cost of this will be about \$750,000, and it will be harmonious in design with those of the Cathedral and Columbia College. One special idea of the new enterprise is to have separate buildings for patients with certain diseases, and it is probable that one devoted to those suffering from phthisis will be erected as soon as the necessary funds can be secured.

A NEW HOSPITAL FOR CHILDREN.—The trustees of St. John's Guild have determined to establish a small hospital for children in West 61st Street, and if this movement is successful, and the necessary funds are forthcoming, they propose to open other branch hospitals of a similar character in the most densely populated portions of the city.

PHILADELPHIA.

RESIGNATION WITHDRAWN.—Prof. Wm. Goodell tendered his resignation of the Chair of Gynecology in the Medical Department of the University of Pennsylvania, February 11th, but at the request of the Trustees, has consented to withhold it, provided his duties are lessened, as the demands of his large private practice forbid his devoting so much time as he has been giving hitherto to college and hospital work.

PROFESSOR WOOD'S TESTIMONY IN THE HARRIS CASE.—Prof. Horatio C. Wood made a personal statement at the last meeting of the College of Physicians, which calls attention to a remarkable and too prevalent abuse of privilege. In a recent trial in a New York City Court (the Harris Case), Professor Wood was called upon to testify as an expert on opium-poisoning. When he read the report of his testimony in the New York papers the next morning, he found statements attributed to him which to his mind could only be explained on the theory that he was mentally irresponsible at the time of making them. He was very much concerned about the matter, and immediately returned to New York to see if it was too late to have the testimony re-opened, so as to make his testimony read as he had intended to make it. Upon reaching the office of counsel he asked to see the official stenographic report, in which he found his replies, to hypothetical and scientific questions, perfectly correctly recorded. He arrived at the conclusion that the reporter, who had written the account of the trial, was not present in court when his testimony was given, and wrote a fictitious and misleading statement. What Dr. Wood did state is as follows:

"The positive diagnosis of opium-poisoning from the symptoms alone, is often impossible. In the Har-

ris case, the symptoms as embodied in the hypothetical question were so loosely observed that many symptoms essential to the diagnosis are omitted, and to this is added the fact that the early development of complete coma as recorded, is conformable to natural diseases, and is extremely rare, if it ever be present, in opium-poisoning. It seems to me that the cause of death, so far as the medical testimony is concerned, is enshrouded in an impenetrable mystery."

THE NEW LABORATORY OF HYGIENE OF THE UNIVERSITY OF PENNSYLVANIA is to be opened on February 22d, with appropriate ceremonies, and a large number of guests have been invited to inspect the new building and its complete equipment. It is very clear that the course is to be eminently practical. Every part of the building is a hygienic object-lesson; all the most approved methods of heating, lighting, draining and ventilating are to be tested by actual use. One room has six varieties of steam radiators, arranged so that the efficiency of each, and others, if necessary, can be known by accurate measurement. Another room exhibits three systems of ventilation. All sorts of traps and water-closets will be tested in the building. All pipes for drainage, hot and cold water, steam and gas, have everywhere been left bare; each system has its own color, so that it may be readily traced. In many of the laboratory fittings, there are new features especially adapted to the novel work to be done. The construction has been continually under the supervision of Dr. John S. Billings, who will be the Director of the School, and it appears certain that nothing which could add to the efficiency of the course has been omitted. Besides the course in Practical Hygiene, there will be an elementary course in Bacteriology, commencing at once, and an advanced course commencing April 2d, each lasting eight weeks. These courses are intended to be practical and will include investigations of water, air and soil, the study of pathogenic bacteria, microscopic technique, culture media, protective inoculation, and the preparation of vaccine, also details of disinfection, antisepsis, etc. Dr. A. C. Abbott, recently Assistant in Bacteriology and Hygiene in the Johns Hopkins Hospital in Baltimore, has been appointed First Assistant in the Laboratory of Hygiene, and applications for information or admission should be addressed to him at the University of Pennsylvania. This is the department which was founded through the liberality of Mr. Henry C. Lea and others. It is a valuable acquisition to the University.

THE PENNSYLVANIA HOSPITAL.—The Board of Managers of the Pennsylvania Hospital has approved plans for constructing a new wing, which will increase the capacity of the institution by one hundred beds, and will involve the expenditure of some three hundred thousand dollars. It is also contemplated to build a three-story Nurses' Home on the grounds, at a cost of forty thousand dollars, and plans for a new out-patient department are being prepared. Although this is probably the oldest general hospital in this country,

and its managers almost without exception members of the Society of Friends, who are celebrated for conservative methods, this hospital is in excellent sanitary condition; has many modern appliances, and is unsurpassed in its results; in fact, it is fully abreast of modern practice in both medicine and surgery. Clinical instruction to medical students has always been a feature of this institution, lectures being delivered on Wednesday and Saturday mornings. It also owns one of the largest medical libraries in the country, which can be used by physicians or students by the payment of a nominal fee each year.

NEW HOSPITALS.—A new hospital was opened on North Broad Street on February 1st, known as the Samaritan Hospital, which is a small general hospital under the special care of the Baptist denomination. The Rush Hospital for Consumptives on Pine Street corner of 22d Street, was recently opened, with a view to the special treatment of this unfortunate class, for whom also a cottage hospital at Germantown, in the suburbs of the city, has been in operation for some years.

A SYMPOSIUM ON INFLUENZA was recently held at the College of Physicians by the Philadelphia County Medical Society. Papers were read by Drs. F. P. Henry, H. A. Hare, L. F. Flick, Roland G. Curtin and Charles K. Mills.

A UNIQUE OPERATION.—Prof. Wm. H. Keen, on the 4th inst., performed an amputation at the hip-joint upon a lady who was suffering with rapidly-growing sarcoma of the thigh, and who had been sent from Brazil to see what could be done for her relief. What makes the case probably unique in surgical annals, is the fact that she was in the fifth month of pregnancy at the time of operation. The arteries were controlled by Wyeth's method, and scarcely any loss of blood occurred. Last accounts showed entire absence of fever, and patient doing well. A detailed report of this case will be published soon.

THE SEVENTH ANNUAL REPORT OF THE STATE BOARD OF HEALTH AND VITAL STATISTICS has just been issued by the Secretary, Benjamin Lee. The prospect of obtaining statutory enactments from the present Legislature in order to place the work of the Board upon a firmer basis, confirm its powers, and increase its usefulness by increasing its pecuniary means, appears to be better than ever before. This is largely due to the fact that the Board did such good work at Johnstown, after the flood in 1889, that Governor Beaver in his Annual Message to the Legislature, January 5, 1891, strongly commended the work of the Board, and urged the Legislature to make increased appropriation. He directed particular attention to the pollution of streams and water-courses, and the problem of the disposal of sewage of densely settled communities. The Board has appointed a Committee to consider the expediency of memorializing Congress on behalf of a National Law to prevent the pollution of streams passing from one State to an-

other, and this subject will probably be discussed at the National Conference of State Boards of Health, which meets next summer in Detroit.

Miscellany.

LOCAL ANÆSTHESIA.

HR. C. SCLEICH, at a recent meeting of the Berlin Medical Society, discussed the subject of local anesthesia by subcutaneous injections. He recommends that the skin be sprayed with ether before the puncture. Cocaine should be used in weak solutions only; he has performed five laparotomies with a .2 per cent. solution. The strictest antisepsis is necessary. Even solutions of two parts in 10,000 make the skin insensible in the region of the puncture; even water injected into the skin produces anesthesia. That water acts because it is a chemically foreign body is shown from the fact that a physiological neutral fluid fails to produce similar results. Other solutions which are capable of producing anesthesia are solutions of sugar, one per cent. solution of methyl violet, one-tenth per cent. solution of morphia, two per cent. solution of bromide of potassium, and two per cent. solution of caffeine.

These latter two solutions he recommends in cases where as much cocaine has already been injected as is deemed safe. In the discussion on this paper Gluck said that he considered that in some cases of similar local anesthesia the patient was in a condition of hypnosis.

THERAPEUTIC NOTES.

THE SALTS OF STRONTIUM.—A great deal has recently been written in the French journals on the therapeutic value of strontium. Germain Sée¹ has, noticing that in cases of Bright's disease, digestive troubles were often very much benefited, tried the effect of bromide of strontium in different forms of gastric troubles in doses of from half a drachm to a drachm a day. Different forms of dyspepsia were much benefited by its use. He suggests that the iodide of strontium may with advantage be substituted for the iodide of potassium in cases of heart disease.

Dujardin-Beaumetz² has employed the lactate of strontium with very good results in cases of Bright's disease. He attributes this favorable action to the effect of the salts on the digestion.

CREASOTE IN PHTHISIS.—Somnerbrodt³ again advises the use of creasote in pulmonary consumption. Five years ago, he published his results with it in a number of cases in which the maximum daily dose was less than eight drops. He is now convinced that it may be given in much larger doses. He reports several cases in which he has obtained very good results by a daily dosage of from a quarter to one drachm. He advises that it be prescribed in gelatine capsules, each containing one and one-half drops in combination with cod liver oil. At the commencement of treatment it may be sometimes necessary for a time to suspend its administration on account of gastric disturbance.

Correspondence.

THE MURAL PAINTINGS AT THE PARIS SCHOOL OF MEDICINE.

MANCHESTER BY THE SEA, MASS.,
February 12, 1892.

MR. EDITOR:—Those who have attended lectures at the School of Medicine, Paris, will remember the beautiful mural paintings, to the right and left of the rostrum in the amphitheatre. The mottoes were: "Ils étanchent le sang consacré à la défense de la patrie," "La bienfaisance du souverain hate leur progrès et récompense leur zèle," "Ils tiennent des dieux les principes qu'ils nous ont transmis." I write to ask if any of your readers know where I can obtain copies of these paintings, which are now in the past, as the amphitheatre was destroyed by fire two years ago.

Very truly yours,

W. T. PARKER, M.D.

A SURE CURE FOR EPILEPSY.

We have received the following letter from Michigan:

—, MICH., February 7, 1892.

BOSTON MEDICAL AND SURGICAL JOURNAL.

Gentleman, Dear Sir:—Will please publish few lines in your journal, and oblige that I have made a discovery and positive cure for Epilepsy. I claim that I can cure any case of Epilepsy, I don't care of how long standing. I have used this remedy now for 8 years in my practice and for the last 14 months I have made a speciaal business of it; and have treated a number of cases. I have cases treated and cured by my medicine 8 years ago. And from that time on till to the present. I will give you some cases treated of late, one lady 40 years had fits for 37 years every 2 weeks. She commenced taking my medicine one year today and she never had a fit after she commenced taking my medicene. Another lady 15 years old had fits for 10 years every 2 weeks. She commenced taking my medicine 17 months ago and she never had a fit after she commenced taking my medicene, she took medicine 7 months then stoped it off. As a rule will take 9 month to perfect a permanent cure. Which I can tell only after the patient has commenced taking my medicene. I have stoped them of at 6 month etc. Another gentleman 32 years old had fits for 7 years from 3 to 5 times every night. He commenced taking my medicene 14 month ago. And in 3 weeks after he commenced using my medicene the fits was entirely arrested and he never had any syptoms of them since. At the time he commenced the treatment, he was almost ready for the Asylum. Another lady 22 years old had fits for 19 years from 3 to 7 times a week, she commenced my treatment 3 month ago, and she is doing all right, had no fits since. Another I am sorry to say is a Brother doctor of the east Penn had fits for 13 years. He commenced taking my treatment 5 months ago, and is doing all right. He had a one fit after he commenced taking my medicene. I only had 3 cases of all the patient I treated that had any fits after they commenced taking my medicene. And so on I could tell you of lots of other treated with the same results. I have kept my medicine a secret so far and will yet for a while. I shall make a disclosure in the fortune with the practice and experience. I had had I came to the conclusion to publish it to the profession. And the world. I have so much faith and confidence in my remedy, If any body doubt my curing effects, I will make a written contract with the patient to cure him or no pay. I know that I can do more good with my remedy than anything else that ever was prescribed in the way, treating Epilepsy. The medicene can only be got directly from me. It will not be sold by druggist.

Yours Truly

DR. ——————

METEOROLOGICAL RECORD,

For the week ending February 6, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 2,680: under five years of age 890; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 326, acute lung diseases 503, consumption 310, diphtheria and croup 131, scarlet fever 71, typhoid fever 35, diarrhoeal diseases 22, whooping-cough 19, cerebro-spinal meningitis 15, erysipelas 10, puerperal fever 3.

From diarrhoeal diseases New York 11, Philadelphia 5, Lowell 2, Cincinnati, Cleveland, Washington and Worcester 1 each. From whooping-cough New York 1, Boston and Pittsburgh 3 each, Philadelphia and Cleveland 2 each, Gloucester 1 each. From Puerperal fever New York 1 each. From cerebro-spinal meningitis New York and Philadelphia 3 each, Brooklyn and Washington 2 each, Worcester, Salem, Taunton, Gloucester and Quincy 1 each. From erysipelas New York 4, Cleveland 2, Brooklyn, Boston, Springfield and Northampton 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,185,736, for the week ending January 23d, the death-rate was 35.4. Deaths reported 6,884: acute diseases of the respiratory organs (London) 1,465, whooping-cough 254, measles 124, diarrhoea 41, diphtheria 38, scarlet fever 32, fever 26, small-pox (Liverpool) 3.

The death-rates ranged from 17.3 in Huddersfield to 60.9 in Brighton; Birmingham 27.2, Bradford 20.5, Cardiff 24.5, Gateshead 21.2, Hull 19.1, Leeds 20.3, Leicester 19.1, Liverpool 40.0, London 46.0, Manchester 29.1, Newcastle-Tyne 24.0, Nottingham 23.8, Sheffield 21.8, Sunderland 23.6, W. Ham 30.5.

In the thirty-three lesser towns of England and Wales with an estimated population of 10,185,736, for the week ending January 30th, the death-rate was 32.1. Deaths reported 6,275: acute diseases of the respiratory organs (London) 1,192, whooping-cough 241, measles 92, diphtheria 39, diarrhoea 34, fever 25, scarlet fever 24.

The death-rates ranged from 18.8 in Sunderland to 47.2 in Croydon; Birmingham 19.8, Bradford 20.7, Hull 23.9, Leeds 21.8, Leicester 21.2, Liverpool 33.1, London 41.0, Manchester 27.6, Newcastle-on-Tyne 22.8, Nottingham 26.6, Portsmouth 32.5, Sheffield 20.1.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 6, 1892, TO FEBRUARY 12, 1892.

February 5, 1892. The following named officers, having been found by Army Retiring Boards, incapacitated for active service on account of disability incident to the service, are by direction of the President, retired from active service this date, under the provision of Section 1251, Revised Statutes: CAPTAIN HENRY G. BURTON, assistant surgeon, CAPTAIN ARTHUR W. TAYLOR, assistant surgeon.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING FEBRUARY 13, 1892.

P. H. BRYANT, assistant surgeon, ordered to Naval Hospital, Philadelphia, Pa.

H. T. PERCY, passed assistant surgeon, detached from C. S. S. "Patterson" and granted leave for two months.

C. J. DECKER, passed assistant surgeon, detached from Naval Hospital, Philadelphia, and to C. S. S. "Patterson."

JOHN F. URKE, passed assistant surgeon, ordered to Naval Hospital, Portsmouth, N. H.

HOWARD WELLS, surgeon, detached from Naval Hospital, Portsmouth, and wait orders.

JOSEPH A. GUTHRIE, assistant surgeon, ordered to Naval Station, Port Royal, S. C.

L. L. Young, assistant surgeon, detached from Naval Station, Port Royal, S. C., and to the Receiving-ship "Independence."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE, FOR THE THREE WEEKS ENDING FEBRUARY 6, 1892.

PURVIANCE, GEORGE, surgeon. Detailed as Chairman, Board of Examiners. February 3, 1892.

HUTTON, W. H. H., surgeon. Detailed as member Board of Examiners. February 3, 1892.

SAUTELLE, H. W., surgeon. Granted leave of absence for ten days. January 30, 1892.

IRWIN, FAIRFAX, surgeon. Granted leave of absence for fourteen days. January 26, 1892.

MEAD, F. W., surgeon. Detailed as recorder, Board of Examiners. February 3, 1892.

CARTER, H. R., passed assistant surgeon. Granted leave of absence for seven days. January 20, 1892.

CARMICHAEL, D. A., passed assistant surgeon. When relieved to proceed to Port Townsend, Wash., and assume command of Station. January 23, 1892.

GLENNAN, A. H., passed assistant surgeon. When relieved to proceed to South Atlantic Quarantine and assume command of Station. January 23, 1892.

WHITE, J. H., passed assistant surgeon. Relieved from duty at South Atlantic Quarantine; to assume command of Service at Savannah, Ga. January 20, 1892.

CARRINGTON, P. M., passed assistant surgeon. When relieved to proceed to Evansville, Ind., and assume command of the Service. January 20, 1892.

MAGRUDER, G. M., passed assistant surgeon. Relieved from

duty at New Orleans, La.; to assume command of Service at Portland, Oregon. January 23, 1892.

VAUGHAN, G. T., assistant surgeon. When relieved to report to the Supervising Surgeon-General. January 20, 1892.

CORR, J. O., assistant surgeon. Ordered to examination for promotion. February 3, 1892.

STONER, J. B., assistant surgeon. Ordered to examination for promotion. February 3, 1892.

CONDIT, A. W., assistant surgeon. When relieved to proceed to Wilmington, N. C., and assume command of the Service. January 23, 1892. Ordered to examination for promotion. February 3, 1892.

GARDNER, C. H., assistant surgeon. Assigned to temporary duty at Baltimore, Md. January 27, 1892.

PROMOTIONS.

CARTER, H. R., surgeon. Commissioned by the President as surgeon. January 28, 1892.

VAUGHAN, G. T., passed assistant surgeon. Commissioned by the President as passed assistant surgeon. February 8, 1892.

GARDNER, C. H., of Maryland. Commissioned by the President as assistant surgeon. January 28, 1892.

AN ARMY MEDICAL BOARD.

An Army Medical Board will be in session in New York City, N. Y., during April, 1892, for the examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before April 1, 1892, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from whence they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character and moral habits. The candidate must be between twenty-one and forty-eight years of age, and a graduate from a regular medical college, as evidence of which, his diploma must be submitted to the Board.

Further information regarding the examinations may be obtained by addressing the Surgeon-General U. S. Army, Washington, D. C.

C. SUTHERLAND, Surgeon-General U. S. Army.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—A regular meeting of the Society will be held on Monday, February 22, 1892, in the Medical Library, 19 Brattleton Place, at 8 o'clock P. M.

Dr. T. M. Botch: "Improved Methods of Modifying Milk for Infant Feeding."

Dr. E. Reynolds: "Rapid Methods of Repairing the Pelvic Floor in Primary and Secondary Operations."

G. G. SEARS, M.D., Secretary.

MEDICAL ASSOCIATION OF GEORGIA.—The Forty-third Annual Session will meet in Columbus, Ga., on April 20, 21, 22, 1892.

DAN H. HOWELL, M.D., Secretary, Atlanta, Ga.
G. W. MULLIGAN, President, Washington, Ga.

BOOKS AND PAMPHLETS RECEIVED.

Poliomyelitis with Perineuritis. Tumors of the Brain. By J. T. Eskridge, M.D., Denver, Col. Reprints. 1891, 1892.

Essentials of Medical Electricity. By D. D. Stewart, M.D., and E. S. Lawrence, M.D. Philadelphia: W. B. Saunders. 1892.

Structure of the Rectum. A Study of One Hundred and Thirty-eight Cases. Second edition. By Chas. B. Kelsey, M.D. New York. 1892.

Syphils in Ancient and Prehistoric Times. By Dr. F. Buret, Paris. Translated by A. H. Ohmann-Dumesnil, M.D. Volume I. Philadelphia: F. A. Davis. 1891.

A Treatise on Diseases of the Lungs and Pleura. By the late Wilson Fox, M.D., F.R.S. Edited by Sidney Coupland, M.D., F.R.C.P. Philadelphia: P. Blakiston, Son & Co. 1892.

Consumption: How to Prevent it and How to Live with it. By N. S. Davis, Jr., A.M., M.D., Professor of Principles and Practice of Medicine, Chicago Medical College, etc. Philadelphia: F. A. Davis. 1891.

Addresses.**THE OBJECTS, PLANS AND NEEDS OF THE LABORATORY OF HYGIENE.¹**

EXTRACTS FROM AN ADDRESS DELIVERED AT THE OPENING OF THE LABORATORY OF THE UNIVERSITY OF PENNSYLVANIA, FEBRUARY 22, 1892.

BY JOHN S. BILLINGS, M.D.

FROM those who have preceded me you have heard of the origin of this laboratory, and something of the wishes, hopes, and expectations of the public with regard to it, as indicated by the donor, and by representatives of the University and the State.

You see clearly that this magnificent gift imposes a heavy responsibility upon those who are charged with the duty of managing it, and of seeing that it is so used as to meet the many and various demands which may rightfully be made upon it: and, in attempting to explain to you briefly what the laboratory now is, and why it is as it is, I come before you oppressed with a keen sense of this responsibility, which is not lessened but rather increased by the fact that I feel that I am speaking to friendly critics.

For this new building, with its equipment and resources, is but an implement—a piece of mechanism—which may be used to shape products of vast importance, not only to the world as it is, but to generations not yet conceived; or which, on the other hand, may be so used as to be of little more importance to humanity than the toy tool chest or the doll's house of a child.

What this use shall be depends upon the force and skill applied to it; upon the materials submitted to it; upon the ability of those who guide it to foresee the direction in which at each moment of time it is best to move it; upon the knowledge and patience of those who are working in it; and, when all these are at their best, the results must still depend upon the decrees of Divine Providence, upon circumstances which no man can fully foresee, and which, therefore, no man can, with certainty, control to the end desired.

The position of laboratories in their relations to education, to science, to technology, and to the executive departments of governments and the welfare of the public, has become a very notable one within the last fifty years. A laboratory—or, as it was called in old times, an "elaboratory"—is, as its name indicates, a place for labor, for work—and especially for skilled labor, in the making of delicate and difficult observations and experiments; for analysis, to determine composition and causes; for synthesis, to determine the results of new combinations; for solving old problems, and for stating new ones. It is not a museum, or a store-room, or a show place, nor does this kind of a laboratory offer much for sale, except opportunity.

Only an opportunity—just a few possibilities, offered to the man who desires knowledge, who wants to see, and touch, and try for himself. Yet this offer of such an opportunity is what distinguishes it from those institutions established for the benefit of individuals.

The ideal laboratory of the alchemist or philosopher of by-gone days was a mysterious, dusky place, the operations in which were kept a profound secret, and which thus gained in repute what they could not have obtained by publicity and free criticism.

Laboratories planned and fitted for public use, offering to any one who is able and willing to pay a mod-

erate fee, and to submit to a few simple regulations, not only opportunities for learning the details of the processes carried on therein, but also facilities and means for making special research as he could only obtain otherwise at great expense and loss of time; such laboratories, I say, are all of comparatively recent date.

It is not yet twenty years since the first separate institution of this kind was established for hygiene—and even now there are not more than a dozen such laboratories, specially built and fitted for their purpose, in existence throughout the world. Of these, the best known is probably that of the University of Munich, under the direction of Professor Pettenkofer, while the largest is that of Berlin.

This laboratory is the first structure of its kind erected in the United States, and it therefore opens a comparatively new field of work in this country. What is the nature of this field, and what are its boundaries? The object of hygiene is to preserve and to improve health, and there are few matters affecting the physical, intellectual, emotional, and moral condition of man as an individual, or of men in communities, that may not come within the scope of its investigations. The destruction or avoidance of causes of disease is but a part of its objects—it is at least equally concerned with the means of making a man better fitted to resist these causes. "That kind of health," says Montesquieu, "which can be preserved only by a careful and constant regulation of diet is but a tedious disease." Disease, like health, is a vague term, including widely different and often very complex conditions, processes, and results, which must be observed, classified and described in such a way that different men, widely separated in space and time, may know that they are seeing the same things, and thus may have the benefit of each other's experience.

In its scientific aspects, then—those which relate to definite and precise knowledge—hygiene rests largely on physiology and pathology, the third leg of the tripod being formed by vital statistics; while, in its practical aspects, it must rest on chemistry, physics, and the data of sociology and politics. . . .

The physician deals with sick men, and his first question is, What is the matter with this person? That is, what group of symptoms does he present, and to what derangement of his mechanism are these due? The hygienist deals with two sets of problems—the first relating to men who are not sick, and how their health and vital resistance-power are to be not only preserved but improved and strengthened; the second relating to sick houses, feverish blocks or wards, infected localities—where the first questions to be solved are, What are the causes of this condition of things? how have they found entrance? are they still acting?

In the investigation of causes he must consider not only the immediate or exciting, but also the remote or predisposing; not only those which are preventable, but those which, with our present knowledge, are unpreventable; and thus it is that heredity, race, local meteorology, occupation, and many other circumstances must be studied by him, as well as the effects of food, clothing, habitation, poisons and viruses. . . .

The recent advances in our knowledge as to the action of certain micro-organisms in the production of disease in animals and man have been largely made by laboratory methods, and indicate clearly that the study of bacteria and microzoa, and of their development,

¹ From advance sheets of the Medical News, February 27, 1892.

products, and effects, must be an essential part of the work of an hygienic laboratory, which should provide the peculiar arrangements and apparatus which are required for this sort of work. In fact, several so-called hygienic laboratories are simply bacteriologic laboratories, the interest in this particular branch of investigation having, for the time being, overshadowed all others.

Our laboratory, however, must provide also the means for chemic investigations of air, water, food, sewage, secretions, and excretions, and the products of bacterial growth; for testing the effects of gases, alkaloids, and albumoses of various kinds upon the animal organism; for investigations in the domain of physics pertaining to heating, ventilation, house-drainage, clothing, soils, drainage, etc. . . .

Just at present, research is being specially directed to certain minute animal organisms—the microzoa—such as are found in the blood in malaria and in the skin in certain diseases, and to immunity, especially to that immunity which may be artificially produced.

Experimental investigation is a slow process, and very uncertain in its results.

An experiment may be conceived which seems as if it would give important results. The experiment itself would require only a few moments or a few hours if all the apparatus were ready to produce the required conditions, and to record in terms of weight and measure the results obtained. But to make this apparatus in the best form, and to provide the means of recording, may take a year or more, and in making this preparation a dozen problems will come up to be solved by other experiments. You are pretty sure to discover something new, but by no means sure that it will be what you began to seek. Every discovery opens new questions and indicates new experiments, and the precise shape in which the work presents itself varies with place and season.

We cannot foresee precisely the demands which will be made upon us, or which we shall make upon ourselves, but we do know that we shall want some large rooms in which a dozen or twenty men can be at one time taught how to investigate, working under the eye of an instructor; and also a number of small rooms, each fitted for the work of one or two men who have attained a certain degree of skill, and are engaged in original research. In all of these rooms we shall at times need to use microscopes, gas-heating and steam; there will be vapors and fumes produced; there will be delicate instruments scattered about, and the rooms must, therefore, be light, have abundance of gas, steam, and water, hoods and flues for conveying away fumes, and they must have plenty of fresh air without dust.

Many of the things that will be seen through the microscopes will be rapidly changing form, and we shall need pictures as well as descriptions of their different shapes.

The most useful drawings for our purposes are those made by sunlight, and, therefore, we want photo-micrographic rooms.

We shall wish to test the merits of various articles of house-equipment, such as different patterns of steam radiators, of traps, of sinks, and closets, etc., and for this purpose we must have places where they can be fitted and put into use.

We must know what other investigators in other laboratories, and many places besides laboratories, have done and discovered, that time and effort may not be

wasted. We must, therefore, have the books and journals in which these are recorded, which are already many, and coming rapidly. A small library and reading-room is therefore essential.

Much of the apparatus to be used must be either made or specially fitted and adjusted on the spot to meet special indications which it is impossible to foresee, and, therefore, we need a large workshop, with tools and appliances for working in wood, glass and metal, and with power. . . .

The chief object of the existence of this building is to fit a certain number of men from all parts of the country to investigate and solve the problems connected with the securing of the best health and vigor among our people.

We hope, also, that some increase of knowledge will be made here by the workers in the laboratory itself; but the main point to be kept in view is to provide well-trained, scientific, and practical men for other fields of labor. Dr. Mitchell has said that the true rate of advance in medicine is not to be tested by the work of single men, but by what the country doctor is. So, also—and even more so—advance in practical sanitation is not to be measured by laboratory records, but by what health officers and sanitary engineers are able to accomplish.

Even now we *know* much more than we *do*, and the skilled sanitarian too often finds himself in the position of the unhappy daughter of Priam and Hecuba, who could foretell, but to no purpose.

This laboratory is fortunate in being closely connected with, and in the immediate vicinity of, a great medical school, and of great hospitals. As was said before, one of the essential foundations of scientific knowledge of the causes of disease is minute and accurate diagnosis and pathology, and we are, therefore, in constant need of the best knowledge of leaders in these branches of medical science. The hospital is filled with specimens of the results of such causes, acting on the human body—from one point of view, Nature's experiments with poisons cunningly elaborated in the tissues of the body, or with viruses coming from without, upon blood and bone, muscle and brain. Much of the work of this new department will be connected with the results of these experiments.

The laboratory is also fortunate in being located in a great manufacturing city, where the effects of different occupations, of trades dangerous or offensive by reason of dusts, or of vapors, or of waste products, can be readily observed and the materials for study obtained. There is an immense field for a sanitary clinic here, and in the habitations, the streets, the water-supply, and the sewers of Philadelphia.

These clinics, however, cannot, as a rule, be reported for the press, either lay or medical, since to do so would, to a great extent, defeat their object; the great majority of sick houses and manufacturers must be considered as strictly private patients, and their affairs held as confidential. In the case of public institutions, or of public nuisances, a somewhat different rule may apply.

Practical hygiene is to play an important part in municipal government, to secure the best form of which is now one of the most urgent questions of the day. Many of the questions to be decided by city officials as to water-supplies, sewage disposal, etc., require expert knowledge to answer.

Of course, the subject of hygiene and the work of a

university department devoted to the increase and diffusion of knowledge in sanitary science extends far beyond the experiments and demonstrations for which this laboratory is specifically fitted.

Bacteriology, chemistry, pathology, physics, and medical and vital statistics give us the foundation, but sociology and jurisprudence must also be studied in their relations to sanitation to obtain the best results.

It is in and to the home and the workshop that these results are to be applied, and he who aspires to be his brother's keeper, must know how his brother lives.

Labor questions, education questions, maritime and inter-state commerce questions, and methods of municipal finance and government, are all intimately connected with matters of personal and public hygiene, and economic consequences, as well as health, must be considered in the advice and regulations of the sanitarian.

I count it as fortunate, therefore, that there is a law school and a school of finance and political economy in this University to which the Department of Hygiene can look for advice and friendly criticism when these are needed, as they surely will be.

And now a very few words as to the needs of the laboratory. First of all it needs men — men thirsting for knowledge, and fitted by previous training and education to come here and acquire that knowledge, not merely the knowledge that exists in books or that the teachers in this laboratory may possess, but that which is yet unknown, the weight of that which no one has yet put in the balance — the shape and size, and powers for good or evil of things the existence of which has not yet been demonstrated — men who will patiently and earnestly seek the answers to the questions, "what?" "when?" and "how?" in the hope that thus they may by-and-by obtain some light upon the more difficult problems of "whence?" and "whither?" even if they may never be able to answer "why?"

There are not many such young men whose tastes will be in the direction of these lines of research, and of these there will be very few who will have the means to support themselves while engaged in the work. We need, therefore, the means to help them in the shape of half-a-dozen fellowships, paying about five hundred dollars a year each, and granted only to those who give satisfactory evidence of capacity and zeal.

The second thing we want is a demand on the part of the public for really skilled, well-trained sanitary investigators and officials, such as we hope to send out from here; we want a market for our product; we want the legislators of this and other States, and of our rapidly-growing municipalities, to be educated to appreciate the importance and practical value of such health officials, and to give the best of them employment.

Thirdly, the laboratory wants the coöperation and assistance of sanitary authorities and inspectors, and especially those of this city and State.

It needs to know from time to time what they are interested in and are working at, to have the opportunity of showing to its students cases of special interest — sick houses, localized epidemics, special forms of nuisance.

And, on the same principle, and for the same reasons, it desires to have its attention called to special methods of heating, ventilating, and draining buildings, and especially public buildings, such as schools, hospitals,

prisons, churches and theatres, and to matters connected with the hygiene of manufacturing establishments and special occupations, methods of disposal of offensive or dangerous waste-products, of protecting workmen against dust, gases, etc.

In short, we want to know how these things are managed by the men who have a practical interest in them; and if, in our turn, we can suggest improvements, we shall be glad to do so.

Fourth, the laboratory wants a reference library as complete as it can be made, and always up to date. Many of the books and journals required must be purchased, and for this purpose a special fund is needed, but many of the works required can only be obtained by gift.

Thus, we want all the reports of boards of health — State and municipal — of municipal engineers, water-works and water commissioners, park commissioners, etc.

We want the catalogues and circulars of all manufacturers of heating and ventilating apparatus, of plumbers' supplies and house fixtures, of electric and gas fixtures, of machinery and apparatus connected with water-supply and sewage-disposal.

We want copies of plans and specifications of large buildings of all kinds.

And these things can only be obtained through the aid and good-will of manufacturers, engineers, architects and sanitarians all over the country; and this aid I venture to ask, feeling sure it will be granted by those who know what is wanted.

I will mention but one more special want to-day, and that is of means for the proper publication of illustrated reports and accounts of the work done in the laboratory.

In the meantime we must be patient, and not too eager to touch the fruit of the blossom that is not yet blown.

In the chambers of this laboratory are to be explored and tested some of the strangest and subtlest of the manifestations of force which surround and are within us.

Here we are to deal with problems of life and death, to seek to unravel some of the webs which bind and choke our children, and which make our strong men helpless, that we may for a time, at least, put these trammels aside or sever them.

I dare not attempt to promise or to prophesy as to the work which will be done here, or as to the future of this new department of the University.

Those who are to be connected with it may not do the best that can be done, but at least they must do the best they can, and, if needful, give place to others who can do better.

Those to whom we owe this laboratory and its equipment and endowment, have been generous and wise in their generosity, which has been in accord with the teaching of the son of Sirach, "Having grace in the sight of every man living, and detained not for the dead."

Death comes by many paths to one or other of the three porches of the microcosm through which he enters, and brings his poppy flowers to all doors soon or late; but if we knew that which we might know, and did that which we might do, he would be preceded by fewer heralds of suffering, and would arrive only when we were ready to be "hushed in the infinite dusk."

If "ye shall know the truth, the truth shall set you free"—not free from change, or from grief, or from the final passage beyond the veil, but free from causeless fears, from unnecessary pain, from useless labor; and this is a part of that wisdom "which passeth and goeth through all things," and is "the brightness of the everlasting light, the unspotted mirror of the power of God."

ADDRESS

DELIVERED AT THE OPENING OF THE LABORATORY OF HYGIENE OF THE UNIVERSITY OF PENNSYLVANIA,
FEBRUARY 22, 1892.

BY BENJAMIN LEE, A.M., M.D., PH.D.,
Secretary of the State Board of Health of Pennsylvania.

MR. PROVOST, LADIES AND GENTLEMEN: — I trust there is no one present on this memorial day and this auspicious occasion whose bosom does not swell with patriotic pride at the thought that he is an American citizen.

Recalling, as we are wont, the virtues of him whom, above all others, we are accustomed to regard as the founder of our liberties, let it be a part of our grateful observance to sum up the blessings which flow from them. And that we may the better appreciate them, let us compare the wretched lot of the denizens of cities of the old world, groaning under the iron heel of despotism, with our own more highly favored circumstances. The tyrannical rulers of those down-trodden people actually presume to interfere with their meats and drinks, — forbidding them to quench their thirst with water enriched by the sewage of cities, hallowed by the infusion of the remains of their dead ancestors, or delicately tinted with the drainage of coal mines; or to refresh themselves with beer rendered aromatic and enlivening by cocculus indicus and strychnine, or wine manufactured from the juicy apple and the generous turnip, or tea composed of rotten leaves and catechu and colored with verdigris, or coffee innocent of Java and Mocha, or chocolate in which the offensive cocoa-butter has been entirely replaced with tallow. They are not permitted to eat the flesh of tuberculous cattle and trichinous swine, while we are freely allowed to feast on those which have been condemned for their markets. Even the little children are forbidden the delights of sucking candy brilliant with arsenic, or munching buns beautified with chrome yellow. The very air which they breathe is deprived of the fragrant and nutritious elements which we enjoy in ours by the removal of manure and other putrefactive substances from the streets before they have had time to pulverize or decompose.

If they desire to ride in public conveyances, they are compelled to obsequiously sit, instead of having the opportunity of athletic exercise and muscular development by hanging on to straps suspended from the roof of the vehicle; or if, perchance, they prefer their own equipages, they have no escape from the dull monotony of smooth and noiseless pavements, so different from our charming variety of cobble-stone and car-track, of hillock and hollow. Thus these unfortunate are hedged in on every side by onerous ordinances and petty infringements of their liberties. When we add the humiliating fact that those who govern their cities and inflict these burdens upon them are men of their own race and nation, instead of being of alien birth or parentage, what is needed to complete the picture of

their misery or to demonstrate the immense superiority of our free institutions? As a result of the admirable training which we receive from the foreigners in authority over us, we have acquired to a distinguished degree the divine virtue of patience; so that an American citizen is recognized at once all over Europe by the lamb-like way in which he submits to physical inconveniences and pecuniary impositions.

But lest this hurried *r  sum  * of our causes for exultation should make us too vain-glorious, I would ask your attention for a moment to a feature of the republican form of government which is, perhaps, less encouraging.

It has been said in regard to our legislative bodies, that, as a fountain cannot rise above its source, so we cannot expect in our legislatures a higher degree of intelligence and education than the average of that possessed by all classes of the population, whom they represent, by whom they are elevated to office, and whom they fear to offend.

It follows from this that legislation of what may be termed the higher order, which recognizes the arts and sciences, and aims to lift the people to a higher plane of culture and civilization, and which is founded on the most recent revelations of science, is not to be expected of our municipal and State legislators. And, indeed, so true is this of our own State, that a clause exists in the constitution forbidding the outlay of the public funds for any such purposes. Hence, if institutions of learning of a high grade or devoted to specific objects are to exist among us, they must owe their origin, and to a great extent their support, to the public spirit and generosity of private citizens. Perhaps this is not an unmixed evil. Perhaps it is well that in the mad haste to get rich quickly, which characterizes our people, there should be a constantly present condition which evokes brilliant examples of public giving as contrasted with individual grasping. Certainly magnificent instances of such liberality exist all over our broad land, and, perhaps, nowhere have more frequent benefactions of this kind increased the opportunities of a great institution of learning, than have of late years been poured into the lap of the venerable University who has called us together to-day to rejoice with her over the reception of her latest gift, and the opening of the newest and loveliest flower in her coronal.

At a regular meeting of the State Board of Health and Vital Statistics of the Commonwealth of Pennsylvania, held November 12 and 13, 1891, a communication was received from the trustees of this university announcing the early opening of its new Laboratory of Hygiene, and presenting a brief curriculum of its proposed line of instruction; whereupon the following resolutions were adopted:

"Resolved, That this Board has received with sincere satisfaction the formal announcement of the approaching opening of the Laboratory of Hygiene of the University of Pennsylvania, considering that this event marks an era in the progress, not of science only, but of civilization in this State.

"Resolved, That the secretary be instructed to communicate with Dr. William Pepper, Provost of the University, and with Dr. John S. Billings, Director of the Laboratory of Hygiene, suggesting a conference for the purpose of formulating a plan by which this Board may avail itself practically of the facilities to be afforded by the laboratory for the investigation of

disease, and of the means for its prevention, for the analysis of foods, water and other beverages, and for bacteriological studies.

"Resolved, That in a definite co-operation between the University and the State Board of Health in the prosecution of such researches, this Board recognizes an opportunity, not only for mutual aid, but for advantage of the greatest moment to the entire Commonwealth."

In accordance with the above resolutions, such a conference has been held, and to me has been assigned the duty of briefly stating the conclusions which were reached, premising, however, that they have not as yet been submitted to the trustees, and may be to some extent modified before either body is called upon to consider them.

The necessity of a Laboratory of Hygiene to the State Board of Health has been urgently felt, and arises out of the duties imposed upon the latter by Section 5 of the Act of Assembly establishing it, which reads as follows:

"The State Board of Health and Vital Statistics shall have the general supervision of the health and lives of the citizens of the Commonwealth, and shall especially study its vital statistics. It shall make sanitary investigations and inquiries respecting the causes of disease, and especially epidemic diseases, including those of domestic animals, the sources of mortality, and the effects of localities, employment, conditions, habits, food, beverages and medicines on the health of the people. It shall also disseminate information upon these and similar subjects among the people. It shall, when required by the governor or the legislature, and at such other times as it deems important, institute sanitary inspections of public institutions or places throughout the State."

Now, to carry out in any adequate degree, the purposes of the law with regard to investigating the causes of disease, and the effects of foods, beverages and medicines on the health of the people, two things, among others, are absolutely essential: first, that the Board should have means and opportunities for making or procuring chemical analyses; and secondly, that it should have means and opportunities for prosecuting what are now known as bacteriological examinations—the study of the germs of disease. And, it goes without saying, that where the interests of the health and lives of five million people are concerned, these means and opportunities should be on a generous scale, and should conform to the most recent developments of scientific hygienic research, both in this country and in Europe. It does not at all meet the intention and requirements of the statute, that the Secretary of the Board should spend a few cents on test-tubes and chemicals, or press his old Dolland microscope, handed down from a previous generation, into the service of the State. Nor, is it fitting that this great Commonwealth, with its millions of revenue, should be depending, as it has done, I say it with burning cheeks, on the charity of private chemists, who have, in a spirit of generous patriotism, placed their services at the disposal of the Board in order to enable it, in some slight degree, to meet the claims that are constantly and properly made upon it, for the analysis of suspected waters and foods. It is hoped, therefore, that the trustees will see their way clear to allowing the Board to refer applications of this kind to the laboratory for investigation. The Board, for its part, will make

every effort to obtain from the legislature a reasonable appropriation for such purposes, distinct from its general appropriation, which will enable it, to meet at least, the cost of all work done for the State.

Further, Section 9, of the Act creating the Board, instructs it, "from time to time, to engage suitable persons to render sanitary service or to make or supervise practical and scientific investigations and examinations requiring expert skill, and to prepare plans and reports relative thereto." Observe the phrases: "suitable persons," "expert skill." Heretofore the Board has been compelled to call to its aid for these objects simply medical men, intelligent, educated, sound practitioners, but without that special training and equipment which would render them "suitable persons" in any strict, technical, construction of the expression, or would furnish them with "expert skill." Here, again, the laboratory will prove the right hand of the Board, giving just that instruction which a sanitary inspector needs to fit him for his special work. And, on its side, it will be the object of the Board to pursue more persistently than it has in the past, its purpose of obtaining a thorough sanitary organization of the State under legislative sanction and compulsion, the result of which will be to create a constantly increasing demand for just such trained practical sanitarians as this school will graduate. In this view of the case it might be the part of wisdom for you, gentlemen, trustees, to place a certain number of scholarships at the disposal of the Board.

Finally, it is desirable that publicity should be given to the important work which will be carried on in this institute, which, I risk nothing in saying, after a careful inspection, and after comparison with other similar laboratories, will be far in advance of any in this country, and the peer of any abroad; it is highly desirable, I say, that this work should be frequently brought to the notice of the legislature, the medical profession and the public; and I therefore suggest that its director present a stated report, quarterly, or at such interval as may be deemed expedient, to the State Board of Health, of all investigations here prosecuted directly in the interest of the public health, which report shall form a portion of the annual report of the Board, to be transmitted to the governor, and of which a certain number of reprints shall be furnished to the trustees for general distribution, as well as for preservation in the archives and various libraries of the University.

The edifice whose inauguration has drawn our willing feet hitherward, ladies and gentlemen, is a temple of Hygieia in a true sense than those fair structures whose marbles flashed back the morning light on the hills of Greece and Rome.

It is in honor of the "sweet, smiling Goddess of Health" that we have met.

The ancients were right in making the divinity whose especial care was the bestowment and maintenance of health, a feminine conception; since woman, as the wife, the mother, the nurse, has for her special function that daily ministry to the bodily welfare of husband and of offspring, that constant presence in and care of the home which are the two essentials to health in the individual and in the family. Her embodiment must needs have been youthful, as presenting ever to the mind of the entranced beholder that period of life when a blood unvitiated by vice or excess courses through a frame unmarred by violence or exposure, and colors a cheek unstained by sin. Purity

must look forth from her eyes and truth sit enthroned on her brow, for unbridled passion and soul-torturing deceit are alike inimical to perfect health. Her form must be lithe, vigorous and well nourished, but not redundant, as warning her devotees that neither asceticism on the one hand, nor gluttony or voluptuousness on the other, are allowable in her worship. Cheerfulness must radiate from her every feature, for gloom and despondency are the recognized foes of sanity, whether of body or mind; and over all, pervading expression of face or pose of limb, must be that indescribable charm of gentleness, as teaching her votaries that in the mutual interchange of kindly sentiment and act, they shall greatly promote the common health and the common weal. And so has the charming inspiration come down to us, immortalized by the sculptor's cunning hand, — a frank and joyous maiden, full of tender grace, robed in chaste and flowing vestment. The fabled daughter of Esculapius, her temple ever nestled under the shadow of his loftier fane, as does that which we dedicate to-day, and her lovely image was sometimes seen in the same shrine even, side by side with his severer figure.

May I be pardoned for appropriating to her praise the beautiful sonnet of America's most American poet, although addressed by him to a sister divinity whom also we glorify on this national anniversary?

"Who cometh over the hills,
Her garments with morning sweet,
The dance of a thousand rills
Making music before her feet?
Her presence freshens the air,
Sunshine steals light from her face,
The leaden footstep of care
Leap to the tune of her pace.
Fairness of all that is fair,
Grace at the heart of Grace!
Sweet "no" to sin and of hall,
Bringer of life out of naught,
Hygiea, oh, fairest of all
The daughters of Time and Thought!"

THE CARE OF WOMEN IN PREGNANCY.¹

BY CHARLES M. GREEN, M.D.

It is probably true that the great majority of pregnant women are not seen by their physician professionally until he is summoned to attend them in labor. If serious complications arise during the pregnancy, such as excessive nausea and vomiting, uterine hemorrhage, unusual pain or convulsions, the doctor is necessarily summoned; but the minor ills and discomforts are endured in silence, and no advice is taken except that of relatives and neighbors, who love so well to fill the ears of the young gravida with accounts of their own experiences. In other words, in the great majority of cases, no attention is paid to the hygiene of pregnancy, and the woman arrives at term in good, bad or indifferent condition, as the case may be.

The reasons for this unsatisfactory state of things are not far to seek. Many women believe that pregnancy is a more or less pathological process, and assume that its ailments must be borne as a necessary concomitant of childbearing. They do not know that most of the ills of gestation are preventable, or largely

remediable, by competent medical supervision and advice, and that so far from being pathological, pregnancy is indeed a physiological process, except in occasional instances. Again, probably a large majority of women are ignorant of the fundamental laws of health, and, while perhaps seldom very sick, are seldom quite well. When, in such women, pregnancy supervenes, it is not surprising that it is often attended with pathological conditions. To ignorance, then, both of the ways of correct living and of the advantages of proper advice during pregnancy, must be ascribed largely the unsatisfactory condition in which many women are found when labor overtakes them.

Another reason for the lack of medical supervision during pregnancy is the attendant expense. The great majority of women are attended in labor by contract, so to speak; that is to say, they expect to pay a certain definite fee, usually a small, inadequate one, which shall cover the doctor's attendance during the labor and his subsequent visits during the convalescence. If the woman desires, or feels that she needs, to consult her physician during her pregnancy, she usually seems to take it for granted that advice at such times should involve no additional fees. It is not surprising that for the very small fees for obstetric attendance that obtain in most suburban and rural districts, medical men should be sometimes unwilling to extend their advice over the pregnancy as well as to take charge of the labor and convalescence. On the other hand, most women are unable or unwilling to pay fees for advice on matters relating to their pregnancy.

For one or more of these reasons, to repeat my original statement, the great majority of pregnant women receive no medical advice or supervision. I believe this to be a misfortune, and a detriment to the best interests of the race; and it is the object of this paper to point out the importance, necessity and advantages of proper supervision of pregnancy, how in my opinion it should be exercised, and how the obstacles in its way can be removed.

There is, supposedly, no question but that pregnancy and parturition ought to be, and were in the divine plan intended to be, physiological processes: that in a large proportion of cases they are not so, a somewhat extended experience leads me to believe. Making due allowance for the congenital and acquired defects of general or local character which are certain to make these processes pathological, the fact still remains, in my judgment, that, in a great majority of cases, pregnancy and labor can be brought quite within physiological and normal limits. If this opinion is true, there is no necessity of dwelling on the importance of adopting such measures as will lead to this most desirable end.

The true object of modern medical science is to do away with the necessity of medical art: in other words, the aim of the true physician is to make the further exercise of his profession useless. While the force of this statement is admitted in general, it has not seemed to me that the extent to which it is applicable in obstetric medicine is fully realized. I believe that, accepting the existing states and conditions in which women of the present day are found, very much can be done by competent supervision during pregnancy to bring labor and puerperal convalescence quite near to normal, physiological bounds; whereas experience has abundantly convinced me that to the lack or inadequacy of such supervision much unnecessary suffering

¹ Read before the Boston Society for Medical Improvement, December 28, 1891.

and disaster are due. But to relieve myself of the probable criticism that my expectations of preventive medicine are altogether utopian, let me hasten to add that whatever may be the possibilities of prevention in the field of epidemiology and general medicine by measures of public and private hygiene, the day is doubtless far distant when the services of obstetric medicine and surgery will be found useless.

Supposing the obstacles in the way of medical supervision of pregnancy, —namely, ignorance of its importance and necessity on the part of the patient, and the question of expense on the part of patient and doctor, —can be set aside, let us consider what can be done for the welfare of the young pregnant woman and her prospective offspring, when free and full opportunities for obtaining medical advice are open to her. What are the respective duties of doctor and patient in the premises? Suppose the woman to have passed over one or two menstrual periods, and in the absence of other probable causes of amenorrhea presumes herself to be pregnant: she consults her physician. By a few simple questions he satisfies himself that presumably she is pregnant: is it his duty to proceed to confirm his presumptive diagnosis by a physical examination? In most cases, certainly not. If important plans, as of journeys abroad, of changes of residence or manner of living, are dependent on a knowledge of the woman's condition, it may be necessary to determine, if possible, by physical examination whether pregnancy actually does exist; but under ordinary circumstances it is proper to proceed with a presumptive diagnosis, knowing that time will settle the matter beyond question. But at this time it is important that the physician should make careful inquiry in regard to the patient's general health. Of course, if he has been her medical adviser previously, her temperament, constitution and general condition will be known to him; but if not, he should inform himself on these points, and adopt such measures as may be necessary to promote good general health, and to remedy, as far as possible, constitutional defects. There are some special points, also, on which specific advice should be given: these points will be considered in detail.

Nutrition is a process of great importance in pregnancy, both to the mother and to her child: it is desirable for the mother to be able to put forth all her strength in her labor, and to endure its necessary sufferings with the least possible shock to her system. To this end attention should be paid to her appetite, diet and digestion. Some women during pregnancy have inordinate and perverted appetites, which need to be moderated and controlled. Some purposely restrict themselves unduly, in the hope of thereby retarding fetal growth and of thus having an easier labor. Others for some reason have an insufficient appetite, which needs to be stimulated by proper therapeutic measures. The diet of pregnancy needs differ in no important particular from that which is proper in other phases of hygienic living, unless some special condition requires specific modification. Some authorities believe the food should be especially rich in phosphates, to promote the bony development of the fetus; but it seems reasonable that whatever food is best for the mother may naturally be expected to be most suitable for fetal development. Simple, nutritious diet, in moderate but sufficient quantity, should be advised: candy, pastries and fries should be avoided. The use

of tea, coffee and wine should depend on their effects and on the patient's habit. Some women, who habitually eat too little, may require forced feeding, —a light lunch between meals and at bedtime, of milk, broth, egg-nog, malt, or bread and butter.

Most women at this early period of their first consultation with their physician are suffering more or less with nausea and vomiting, although some happily escape this often distressing symptom. It is not my purpose to discuss the treatment of this affection, which usually disappears spontaneously when the uterus has become an abdominal organ; but rather to express my belief in the importance and wisdom of checking or limiting it in its incipiency. The water which will quench a small blaze will add to the fury of a conflagration; and measures which will control this symptom in the beginning often prove worse than useless when once perverted function has assumed full sway. No one can tell to what end an apparently physiological nausea may attain. While occasionally no therapeutic measure short of induced abortion (and sometimes unhappily not even that) will control this symptom, in most cases simple remedies will suffice to remove it, or keep it within due bounds: it is often found that attention to diet and digestion is all that is necessary. Morning nausea is often proved to be due to a want of nourishment, and is prevented by taking a lunch at bedtime, and another in the morning before raising the head from the pillow. If simple dietary measures do not prevail, the cause should be sought for, and perhaps found, in a displacement or impaction of the uterus, or in an abnormal condition of the cervix: in other cases the cause will be found in a perverted innervation or hysteria. But whatever the cause, it should be found and removed, if possible, before the development of serious results in the patient's condition. A return of these symptoms in the later months should be given special attention.

At the first early interview the condition of the bowels should receive careful inquiry. Not only are most women chronically constipated, but those with whom the function of defecation was previously normal are often disturbed with sluggishness of the bowels in the early months of pregnancy: indeed, constipation is considered by some a symptom of pregnancy in those previously regular. No speedy resort should be had to drugs, but an effort should be made to correct the difficulty by hygienic and dietary measures. The woman should be cautioned not to strain at stool; enemata will suffice to ensure an easy movement when the failure is due to torpidity of the rectum. Much can be accomplished by proper exercise and dietetics; but should such measures fail, others must be employed to insure a regular, daily movement.

The skin is also an important organ of elimination. The better the functional activity of the skin, the less work will be thrown upon the kidneys at a time when unusual demands are made upon them. If the patient has not the habit of daily bathing, the duty of adopting it should be enjoined, the bath to be followed by vigorous friction with coarse towels. Apart from the benefit of stimulating glandular activity in the skin, daily bathing has a sedative effect on the nervous system and tends to promote the functional activity of the bowels, and other digestive and eliminative organs.

Unless the patient has some antecedent affection of the kidneys, there is seldom any disturbance of their function in the early months. Micturition is some-

times frequent, owing to the pressure of the enlarged and anteverted uterus on the bladder, or there may be an irritability of the latter viscus caused by concentrated urine. Women proverbially drink too little water to properly dilute their urine, which is often high colored, of high specific gravity, and excessively acid. This condition is not, of course, peculiar to pregnancy; but it is liable to be aggravated thereby and should receive attention. A glass of water three times a day will often suffice to relieve this condition: failing this, lithia water or acetate of potash may be advised with benefit. Throughout the pregnancy the state of the kidney should be closely watched. By this is not meant that the urine should be examined necessarily at frequent intervals. The patient herself, if of average intelligence, can be taught to do most of the watching, and that, too, without exciting her nervous apprehensions. In these days when water-closets are to be found on every floor of most houses, bedside cabinets and the old-time chamber-vessel are seldom used: as a result, most people rarely see their own urine and are unable to give much information concerning it. It is my custom, therefore, to direct pregnant women to see their urine at least once a day: I instruct them as to the average daily amount in health, tell them that it is important that this amount should be maintained, and ask them to notify me, if they notice any departure from normal standards, either in color or amount. I also ask to be informed of the occurrence of edemas, puffiness of the eyelids, headaches, disturbances of vision, nervousness, and indeed of any symptom of ill-feeling. Twice or three times in the later months it is well for the physician to examine the urine; but even without such examination there is no occasion for apprehension of eclampsia so long as the urine is normal in amount, so long as the nervous system is in stable equilibrium, and so long as there is no apparent indication of central nervous irritation: the mere presence of moderate edema and albuminuria, without other symptoms, does not disturb me in the least, although it makes me watchful.

As may be inferred from the last paragraph, the condition of the nervous system should receive special attention throughout pregnancy. Making due allowance for a poor inheritance, most women can be brought into a state of nerve equilibrium by a skilful guidance on the part of the physician into ways of correct living. There is no better medicine for unstable nerves than a plenty of sound sleep. If, therefore, it is found that the patient's sleeping habits are unsatisfactory, the cause should be sought for and removed. Suitable exercise, and a warm bath and a lunch at bed-time are often efficacious; but sometimes a course of bromides may be advisable. In the later months the woman sometimes fails to sleep because she cannot lie comfortably in bed. She may be accustomed to sleeping on her side, but finds herself unable to lie comfortably on her side when the abdomen is much enlarged. In such cases I have found that the use of a small pillow, upon which the abdomen can rest as upon a shelf, has been productive of comfort and repose. A pregnant woman's nervous system is often grievously upset by the injudicious conversation of her friends and relatives. Some people are singularly, nay criminally, indiscreet in their talks with pregnant women. Accounts of appalling hemorrhages, of convulsions, and of the graver obstetric operations are certainly not conducive to nerve quietude in the preg-

nant state. Neither is it judicious for the gravida to read all about it in the family medical books: such books are responsible for much harm. The more ignorant of the act of parturition a woman can be kept, the better: I would not have her know that there is such a thing as a placenta even. I always advise against any reading or any conversation with friends on the whole subject, and warn against listening to what may be well meant in the way of lay advice, promising that I will answer any question, if it be proper.

If a woman dresses properly at other times, she needs make no changes during pregnancy, except to provide for the gradually enlarging uterus. Most women, however, still cling to the garter and the corset, both of which are more than usually deleterious during pregnancy. It is sometimes difficult to induce a woman to lay aside these abominations even in the later months; but such a course should be advised, and the reasons why should be explained. It is gratifying to know that some women are substituting a comfortable waist for the corset; and are suspending the skirts from the shoulders, instead of buttoning them tightly around the waist. Garters are also to some extent giving way to tapes attached to the corset-waist. It will be the better for all women, when they follow the advice of physicians in these matters of dress.

How much exercise ought a pregnant woman to take? It is often difficult to prescribe the exact amount that is suitable for any given person. Most women obtain all needed exercise in the pursuit of their usual affairs; some, however, in the leisure class, need more than their habitual activity. Walking is probably the most suitable exercise in pregnancy, not carried, however, to the point of fatigue: the august lady at the court of St. James set her subjects a good example in this respect. In the latter weeks, when walking may become difficult, driving may well take its place. One might hesitate to prescribe gymnasium exercise for the pregnant; yet I recall one patient, habituated from early childhood to gymnastic exercise, who continued her training during nearly the whole of her gestation, omitting only the heavier work, and she had a most rapid and easy labor and an uneventful convalescence. Fortunately, most women are engaged in house-keeping duties, and except for the want of the open air housework is probably the healthiest occupation a woman can have. It is difficult sometimes to induce women to take sufficient open-air exercise; but there is no question that most women are greatly benefited by it during pregnancy, and have easier labors in consequence. Women should be willing to train themselves in some degree for their labor, as an athlete would train himself for a race.

Pregnant women should be cautioned against indiscriminate exertion at the times which would be menstrual periods were they not pregnant. I have too often seen the unfortunate results of indiscretions at these times. When miscarriage occurs, it is usually at the time of a menstrual epoch. Some women are made aware of the approach of these epochs during pregnancy by certain unmistakable sensations and feelings of malaise; but to avoid oversight in those not so warned, they should be advised to mark off on their calendars the days when menstruation would ordinarily occur. In these days no undue exertion should be made, and exercise should be somewhat restricted: above all at such times nervous excitement should be avoided.

This leads me to speak of the propriety of sexual intercourse during pregnancy. To many women I believe coitus during pregnancy is distasteful, to many even obnoxious, to all, in my opinion, it is more or less injurious. Aside from the mechanical disturbance of the uterus by impact, the sexual act injuriously congests the pelvic vessels, excites and then depresses the nervous system, and is often a cause of miscarriage, especially when practised at a menstrual epoch. So far as my knowledge of the animal creation goes, the pregnant female will not suffer the sexual approach of the male, but will fight, if necessary, to protect herself. Certainly among enlightened human beings, men who have at heart the welfare of wife and children should be willing to forego sexual indulgence during the time when the wife needs all her vital powers for her own well-being and that of her expected offspring. Many men and women err through ignorance, and are grateful for advice on this subject.

It is believed by some that the pelvis should always be carefully measured in the early months of pregnancy with a view to anticipating some serious complication in labor at full term. In women who have a history of difficult and pathological labors, such a course is wise; but in primigravidae it has never seemed to me warrantable to subject them to a routine examination unless there was a reasonable suspicion of some deformity in the parturient canal. Marked forms and degrees of pelvic deformity are likely to be suspected during pregnancy, if the patient is under observation, and in such cases pelvimetry should be made. The minor degrees of pelvic contraction, on the other hand, even if suspected and ascertained to exist, would not warrant obstetric interference before full term in a woman pregnant for the first time. In such cases the child is often proportionally small, and is safely delivered either by nature or by art. If, however, the first labor proves disastrous, and the woman demonstrates her unfitness to give birth to a full-term child, premature labor can be induced in subsequent pregnancies. I do not, therefore, include pelvimetry among the necessary duties of the medical attendant, as a matter of routine.

With a view to successful lactation the breasts should receive some attention. They should be relieved from injurious pressure by corsets and tight clothing early in the pregnancy; no other care except cleanliness is necessary until after the seventh month when it is advisable to begin to prepare the nipple. The old-time custom of applying a decoction of green tea and brandy in equal parts is familiar to all, and doubtless this mixture is very efficacious in toughening the nipple: I have found, however, that absolute alcohol, diluted one-half with water, is quite as satisfactory and less troublesome. I am accustomed to advise the use of this lotion morning and evening during the last two months. If the nipple is flat or inverted, it is well to draw it out by gentle suction with heated bottle before applying the alcohol. With proper preparation in pregnancy and suitable care during lactation, sore nipples need rarely occur.

As the abdomen enlarges in the later months, and the skin is tightly stretched, much comfort is imparted by anunction with sweet oil or lanoline. I have thought, too, that the skin is thereby softened and made more elastic, and that there is not so much tearing in the deeper layer and consequently not so much disfigurement by scars. Some women are oppressed

with the weight of the uterine tumor and are unable to go about with comfort: a well-adjusted abdominal support is a great comfort in such cases, and often enables the woman to walk and drive until she is brought to bed.

It is well known that a species of anæmia is a physiological condition in pregnancy: the red corpuscles, albumen, iron, and the salts of the blood are diminished; while the white corpuscles, fibrin, and water are increased. Robust, well-nourished women may have sufficient reserve power to sustain the demands which pregnancy makes upon their vital energy without artificial assistance; but this type of women is not common in my experience. I have already spoken of the importance of careful attention to nutrition during pregnancy, as a means of preventing undue impoverishment of the blood; and it has seemed to me that most women are benefited by the administration of iron, especially in the last two months. Apart from the general benefit of iron as a tonic, there is ground for belief that post-partum haemorrhage is less likely to occur in those whose blood has not been too much impoverished by the unsupported demands which pregnancy makes upon it. It has long been my custom to prescribe Quevenne's iron in the last two months of pregnancy, with great apparent benefit.

There remains for me to speak of one more subject of great importance to both patient and physician, the selection of the nurse. Too often this duty is attended to by the patient without consultation with her medical adviser; such, indeed, is the custom. While some men may be indifferent, most physicians would prefer to select the nurse who is to be their lieutenant and assistant, as much as the commanding officer to choose his adjutant, as indeed it is his prerogative to do. It is only right that he who is to have the responsibility of the case should select or approve the nurse who is to carry out his orders: no man can do his best work, if handicapped with an assistant in whom he has not confidence. There is need, I think, of some educational work on this point among the laity: women engage their nurse long before their physician, and without consultation with him, because they have not a correct understanding of the relation of the nurse to the physician. In most cases when the patient's means allow her to employ a training-school graduate, the nurse may be entirely satisfactory to the physician; yet it is unnecessary for me to assert in this presence that there is room for choice among trained nurses. And when we pass without this circle to the greater field of the old-time monthly nurse, we find them good, bad or indifferent, septic or otherwise, according to circumstances. I have long since declined to attend cases unless I could select, or approve of, the nurse, and my own results and peace of mind have greatly benefited thereby: it is needless to add that the patient's welfare is promoted, quite as much as the physician's, by thus allowing the doctor to give his patient the benefit of his own better knowledge as to the relative fitness of nurses. He surely can choose more wisely than his patient.

I hope it will not be supposed, from the length of this paper, that under ordinary circumstances much time or money must be spent in the exercise of suitable supervision over pregnancy. When the woman is in good general health two or three interviews with her physician will usually suffice: at these consultations, distributed through the pregnancy, all needed advice

can be given, and the physician can assure himself that his patient continues well. If, however, at any time the pregnant woman is not well, it is needless for me to emphasize the importance of bringing her as near as possible to normal standards.

It has often seemed to me that the physician's visits came at the wrong time: in most cases he does not see the patient during pregnancy, when he might be of great service, but makes numerous visits during the lying-in period which ought to be for the most part unnecessary. If the patient approaches her labor in good physical condition, in the best possible physical strength and with stable nerves, — if then the labor is skilfully conducted and she is delivered without septic infection and left in the hands of a competent nurse, there is little or nothing to require the subsequent attention of the physician: his care and advice can be much more profitably bestowed before the baby is born. If the physician's visits could be transferred in part from the puerperal to the pregnant period, there would be in my opinion fewer abnormal labors, less suffering, more rapid convalescence and better obstetric results.

How can this desirable state of things be brought about? How can the two chief obstacles be removed? Ignorance of the advantages of supervision among the laity can only be removed by active missionary work by the medical profession: when it comes to be understood in any community that the leading physicians will not attend obstetric cases unless women place themselves under observation early in their pregnancy, the lesson will soon be learned. Already among the more enlightened and well-to-do classes of this community, it is quite generally the custom for women to inform their physician as soon as they have passed over one or two periods and to place themselves in his care. And among those less well-circumstanced the lesson could soon be taught by well-directed effort in the circle of each physician's influence. The question of expense ought not to be an obstacle in the way of all necessary supervision of the pregnant: it is not, among those peculiarly well situated. Indeed, it has seemed to me that less expense is incurred on the average when the patient has received adequate attention during pregnancy, for the reason that fewer visits are necessary during the puerperal period. Among those who by force of circumstances or by custom are attended by contract, where the physician's services must be unrequited, if given during pregnancy, selfish motives alone would seem sufficient to induce him to give all needed attention to prevent complications and disasters which more or less affect his reputation, often give him much additional work and disturb his peace of mind. But appeals to such motives are unworthy of a liberal profession: the true physician is ever willing to give freely of his time and ability to promote the best interests of those who are placed in his care.

A NOVEL OFFENCE AGAINST A PHYSICIAN. — A recent number of *Vratch* quotes a statement to the effect that a St. Petersburg physician was about to prosecute a man who had caused one of the physician's prescriptions for his deceased wife to be posted over her grave, in order to call public attention to his belief that the medicine she had taken had been the cause of her death.

THE ESTABLISHMENT OF SANITARIA FOR PULMONARY DISEASES IN THE VICINITY OF OUR GREAT CITIES.¹

BY VINCENT Y. HOWDITCH, M.D.,
Attending Physician to the Cornhill Hospital, Physician to Out-patient Department at the Boston City Hospital, Instructor in Boston Polyclinic.

The treatment of pulmonary diseases in sanatoria established for the purpose, has been for a number of years a well-recognized method in Europe, especially in Germany, and, during the past few years, the foundation and success of institutions in various parts of the United States, shows that the hopes of those who originated the idea were not vain, and that much more can be done now than heretofore in combating the ravages of consumption.

To Hermann Brehmer should be given the credit of having established the first institution of the sort, about thirty-two years ago, in Görbersdorf, a little village of Silesia, situated in a well-sheltered mountain valley about 1,600 feet above the level of the sea, where phthisis was never known to arise, and where Brehmer himself recovered his health.

He conceived the idea of establishing there an institution to be devoted to the treatment of pulmonary diseases only, and although ridiculed and maligned to an outrageous degree at first by members of his own profession, he finally proved that his views were correct and his name and memory now are honored throughout Germany and elsewhere in the medical world.

Since then, and upon the same principle, the famous sanatorium at Falkenstein, in the Taunus Mountains near Frankfort-on-the-Main was established under the care of Dettweiler, and later, many smaller institutions have sprung up in various parts of Germany, all devoted to the same purpose, and although varying perhaps in details of treatment, they carry out the same general idea that good food, fresh air and strict supervision to prevent the results of indiscretion, in diet and mode of life, are the chief factors in restoring the patients to health. Under these methods both Brehmer and Dettweiler claim that fifty per cent. of the incipient cases of pulmonary disease have been cured.

It was my good fortune in the summer of 1889 to see both of the above-mentioned sanitaria, and I can testify to the great care and pains shown by those in charge of the institutions. Brehmer's sanatorium at Görbersdorf, is a lasting monument to a noble man. Beginning as a small cottage for two or three patients, a little over thirty years ago, the institution now comprises two immense red-brick, Gothic buildings, with accommodations for two hundred or more patients; a large winter garden, reading-rooms, etc., in addition to various small villas scattered about the grounds for wealthier patients. Beautiful gardens surround the houses and a magnificently wooded park with carefully graded paths extending for many hundreds of acres over the sides of the mountains, forms a delightful pleasure-ground for the use of the patients.

In both of these institutions the strictest watch is kept over the general treatment of the patients, in regard to diet, amount and kind of exercise, and methods of life generally. At Görbersdorf, after a light and early breakfast consisting of a cup of tea, coffee or

¹ Read before the Section for Clinical Medicine, Pathology and Hygiene of the Massachusetts Medical Society, Suffolk District Medical Society, December 16, 1891.

milk, with bread and butter, exercise in the open air is prescribed and regulated according to the ability or disability of the patient. When the patient's strength admits of it, a walk up the mountain-side through the park is advised. To facilitate this, paths are laid out with the greatest care at a very gentle grade, seats being provided at many points, and the patients are told to stop and rest frequently to avoid undue fatigue, and at the same time to enable them to get the benefit of increased expansion of the chest and quickened circulation, so important in cases of pulmonary disease. Even in the height of winter is this made possible, as the paths are cleared of snow every morning by eight o'clock, up to the top of the mountain.

About eleven o'clock a more substantial breakfast is served, dinner at two, and supper about half-past six, the intervening time being occupied by exercise or rest in the open air, the patients even in the coldest weather, well wrapped up, reclining in chairs for hours during the day.

The moral welfare of the patients is cared for also, and frequent concerts, readings, games and other forms of amusement make an important feature of the treatment.

The same general methods are carried out at Falkenstein, and although the institution has not yet reached the magnificent condition of Görbersdorf, everything is done for the comfort and welfare of the patients.

It is a significant fact in favor of sanitarium treatment, that although the climate of Görbersdorf differs decidedly from that of Falkenstein, yet the favorable results are about the same in both places. In Görbersdorf they are blessed with infinitely more sunshine than in Falkenstein, which although situated at about the same altitude as Görbersdorf, and on the sheltered weather of a German winter.

Opinions differ at present as to the effects of altitudes *per se* in their beneficial effect upon pulmonary disease; some observers maintaining that it is one of the most, if not the most important factor in the large percentage of cases of recovery reported in regions over 1,500 feet above the level of the sea.

Brehmer himself remarked to me that he believed the altitude of Görbersdorf (about 1,600 feet above the level of the sea) had much to do with his success. Dettweiler, on the other hand, deemed it of much less consequence than other factors. Observers like Solly, Fisk and Denison, in Colorado, are firm in their belief that the altitude of Colorado (over 6,000 feet) is one of the chief reasons of the benefit obtained by the life there, while Dr. Geddings, of Aiken, S. C., whose large experience makes his opinion of much weight, is evidently of the same opinion as Dettweiler.

A discussion upon this point would be of great interest, but it is out of the limits of this paper, as I only wish to speak of the plan of establishing sanitaria for pulmonary diseases in the immediate vicinity of our great cities, in healthy localities, for the benefit of those who can not, or will not, for various reasons, seek more salubrious climates.

The late Dr. Paul Kretschmar, of Brooklyn, N. Y., two or three years before his death, read papers before the American Climatological Association, and before the local New York societies, strongly urging the establishment of such an institution in the hilly portion of New Jersey, near New York, but so far as

I know, no active steps have been taken towards carrying out Dr. Kretschmar's excellent idea.

Very early in my practice I felt that some such institution was needed near Boston, and as the idea grew stronger, I was enabled, with the assistance of Dr. Lovett, to establish, through the generosity of wealthy people here and elsewhere, a small Sanitarium at Sharon, Mass., on the Providence Railroad, a region long known as one of the most healthy localities about here, on account of its gravelly porous soil, its abundance of woodland, and pure water-supply, my idea being to supply to people of very limited means a comfortable home where at the same time a constant medical supervision could be maintained.

The institution was opened last February, and although it is, of course, much too early to give actual results, yet the evidences of the advantage over this method to that of sending patients hap-hazard out into the country to board, are so strong, that I am already convinced that I was not wrong in my first belief that a properly regulated sanitarium would be of the greatest use in our community.

A brief description of the sanitarium will be in place here.

The place selected was a small farm on high land not far from the Sharon station, overlooking a charming view towards the south and west. The soil is gravelly, very porous and dry, well-water not being found above twenty or thirty feet below the surface. Behind the house stretches from east to west a number of acres of woodland, chiefly of pine and hard-wood trees, which, with the line of the Moose hills, form an effective shelter from the harshest winter winds. On three sides of the house extends a broad piazza, in the centre of which, in a recess made on the southern front, the patients can be well protected, even in severely cold weather, when exercising or resting in the open air. The interior of the house is arranged to have as much sunshine and good ventilation as possible; open fireplaces are found in every room, and each patient has her own separate bedroom, no two ever sleeping in the same apartment. The walls are all painted, and are frequently wiped with damp cloths; the floors are of hard-wood covered with rugs, which are frequently cleansed, no laid carpets being allowed. The strictest rules are made as to the sputa of the patients. Cuspidors filled with damp sawdust are on the ground floor, and the contents are burned every day. In the bedrooms small paper cups in frames are at the bedside, and burned after use. When on the grounds the patients carry cloths placed in a rubber pouch in the pocket, the rags being destroyed in the same manner, and the patients are forbidden to expectorate on the grounds or to use any other receptacle than those provided, every effort being made to insure the utmost cleanliness.

The treatment usually pursued is first, that of giving all the good nourishing food possible at the three daily meals, a lunch of milk or raw eggs being taken in the middle of the forenoon and afternoon. Accordinging to the nature of the case, more or less exercise in the open air is taken, and daily rest in reclining chairs on the piazza, even in midwinter, when the sun shines, is one of the most important parts of the treatment, especially in hemorrhagic cases, in which much active exercise either on rising or level ground, is prohibited.

In most of the cases, I have found the tri-weekly or

daily use of the pneumatic cabinet to be of very marked benefit where expansion of the chest is needed, combining it oftentimes with some soothing vapor in cases where symptoms of bronchial irritation are marked. It is in such institutions that this instrument or other methods for expanding the chest and inhaling medicated vapors, can be used with the most beneficial effect, for the patient has the advantage of being near at hand, and can easily take the treatment as often as thought necessary. Judging by the effect in most cases at the sanitarium I regard the pneumatic cabinet as one of the most valuable factors in the general treatment. Tonics are usually given; stimulants occasionally when necessary, but drugs are avoided as far as possible. Everything is done to contribute to the mental welfare of the patients, and drives through the country and both out-door and in-door games are encouraged.

The institution only receives women now, and only cases which are in the first stages of pulmonary disease. We hope, as the project grows, to have cottages built adjoining the present house and to receive both sexes.

The objection has been frequently raised by some, that the effect of putting many patients together is to increase the risks of possible infection, and that the effect upon the patient of seeing others ill about him, will be very depressing and hence deleterious.

That both of these objections have a certain amount of truth in them no one can deny, but that practically, they amount to very little, to those who have had experience in sanitaria, I am convinced.

Before the Sharon Sanitarium was begun, I felt very strongly the force of the latter objection, and one of my first questions to Dr. Trudeau, when I visited his sanitarium at Saranac, N. Y., was, "Do not the patients become depressed by seeing each other ill?" In reply he said, "Listen to that!" and at that moment the sound of some negro songs and very jolly laughter came from a group of patients on the piazza near by, and he added, "That is the way it is all the time. Of course, there are times when each one feels depressed, especially at first, but they usually become accustomed to their surroundings, and if they improve, seem as happy as possible." This was quite in keeping with the sentiments expressed at the large institution at Görbersdorf, by a young American lady who had been there for two years, when I asked her if she never felt depressed at being in a place where there were so many sick people. She laughed and said, "Oh, for the first two weeks I came, I was homesick and of course I felt depressed, but I soon got over that and ceased to think of it, and I am so happy here now I hate to think of leaving, as Dr. Brehmer tells me I probably can in a few months"; and she told me that was the feeling with the majority. My own experience with the patients at Sharon only confirms this idea. They seem very happy; and when depression comes I usually find it attributable to some outside cause and not to the proximity to other patients.

As to the possibility of infection; with proper care I think this danger is reduced to a minimum. No one would deny that the ideal way would be for each patient to have his or her own establishment with a physician in constant attendance to regulate the daily mode of life in the most perfect climate to be found; but as this method is unfortunately impossible for the large majority of sufferers, a less expensive course

must be adopted, and my own belief is that the advantages of the method of treatment I am advocating so far outweigh its possible dangers that the latter practically fade into insignificance.

Dr. S. E. Solly of Colorado Springs, in an admirable paper entitled "Comparative Results of Treatment of Phthisis by Climate,"² gives the conclusions of several of the most celebrated authorities upon pulmonary diseases in Europe and America and by them gives a very convincing proof of the great advantages of treatment in closed resorts (sanitaria) as compared with that in open resorts. In Table III, entitled "Comparison Between Open Resorts and Sanitariums in Low Climates," he gives the following striking figures:

ALL STAGES OF THE DISEASE.

	Cases.	Cured.	Benefited.
Open Resorts in Low Climates,	1,724	4%	46%
Sanitariums in Low Climates,	2,443	13%	27½%

FIRST STAGES OF THE DISEASE.

Open Resorts in Low Climates,	685	5%	46%
Sanitariums in Low Climates,	89	31½%	45%

In thus advocating the establishment of sanitaria in healthy towns near our large cities I do not wish it to be understood that I expect such results as are obtained in climates more salubrious and less trying than our own; but I firmly believe and am daily becoming more convinced from results thus far obtained at Sharon that we can do infinitely more than heretofore to help a large class of patients who are unable for various reasons to seek other climates.

THE ETIOLOGY OF ACUTE PLEURISY WITH EFFUSION.¹

BY GEORGE G. SEARS, M.D.

Or the five cases which are here briefly reported, I have been very kindly allowed to refer to the Records of the Massachusetts General Hospital for the early history of three; while this list could have been easily extended, the five which have been selected illustrate sufficiently the more recent views of the etiology of acute pleurisy with effusion, to serve as a text for its discussion.

Mrs. J. M., aged thirty-six, family history good. In May, 1890, had an attack of pleurisy with large serous effusion for which she was twice aspirated. Nine months previously she had overtaxed herself by nursing a sister-in-law who was in the last stages of consumption and since then had had, at times, a short hacking cough of which she had thought nothing. She recovered sufficiently to perform her household duties, but died a year later of phthisis.

M. H., aged twenty-one, family history unknown, had an attack of pleurisy with effusion, requiring aspiration, in the spring of 1888, from which he entirely recovered and resumed work. In September of the following year, phthisical consolidation of both apices was found.

M. B., aged twenty-one, of good family history, entered the Massachusetts General Hospital in June, 1876, with an effusion completely filling the left side

¹ Read before the Boston Society for Medical Improvement, December 24, 1891.

² Hare's System of Therapeutics, Vol. 1. H. C. Lea & Sons, Philadelphia.

which he attributed to a strain. Six weeks later he was discharged well and resumed his work, that of a stevedore. Six years later he died of phthisis after an illness of over a year.

S. V., aged fifteen, entered the hospital in 1885 with a slight effusion into the left chest following exposure to cold. He had had a slight attack of pleurisy the previous winter. After three weeks he was discharged well, but died four years later of consumption in California, where he had been sent for his health.

Annie L., aged twenty-two, entered the hospital in 1890. Three years before she had had pleurisy with effusion for which she was aspirated. At the time of entrance well-marked signs of phthisis were found in the lungs and she was suffering also from ascites which was ascribed to a tubercular peritonitis. Five weeks later she was so much improved that she was discharged. When she again came under observation, six months later, the pulmonary lesion had advanced and bacilli were found in the sputum, but abdominal examination was negative.

With the exception perhaps of the first case, where the possibility of infection or contagion at an earlier date cannot be excluded, the disease came on suddenly in previously healthy individuals, some of whom were without hereditary taint, ran an acute course and ended in apparent recovery, the patients resuming their ordinary occupations. Later, at periods varying from a few months to a few years, phthisis manifested itself. It is to be regretted that the tubercular or non-tubercular character of the process cannot be definitely settled by an examination for bacilli as in other diseases in which such a suspicion exists, but they have been unsuccessfully sought for with the microscope by Ehrlich, Fraenkel and others in some cases of undoubtedly tubercular origin, while inoculation and culture experiments have proven equally fallacious. Direct evidence is not, however, altogether wanting that primary tubercular inflammation of the pleura may exist. Vaillard's and Kelsch's² cases are very strongly corroborative, but are not quoted here as objection has been made that the bacilli were not sought for. The same criticism cannot be made to two cases reported by Lauth³ in both of which the disease was similar to phthisis, but the autopsies showed tuberculosis of the pleura without previous involvement of the lungs. It cannot be considered positive proof of the tubercular origin of certain cases that they have been followed by consumption after the lapse of several months or years, nor, on the other hand, can its connection with tuberculosis be denied where complete and lasting recovery has taken place. The prognosis in all tubercular affections has been recently so thoroughly modified that cure is expected in a considerable proportion of cases. König, for example, found that out of 131 cases of tubercular peritonitis which he had collected, 30, or about 23 per cent., remained well from two to twenty-five years after laparotomy, and it seems still an open question if this has not shown, by proving the diagnosis, rather than that tubercular peritonitis can be recovered from, than that the operation is in itself always the cause of recovery.

If it could be shown that in a large number of cases a much greater proportion dies of tubercular disease than could be expected from the general average, strong presumptive evidence of the connection between

the two diseases would be furnished and the probability of the tubercular origin of pleurisy be strengthened. Such evidence I have endeavored to procure by collecting all the published series of cases of any considerable size which I could find in the literature of the subject. These have not been very numerous and are not free from several sources of error. Some of the reporters have made no distinction between dry pleurisy and pleurisy with effusion, or have included in their list cases which were secondary to pneumonia, measles or other infectious disease, as well as cases which were under observation too short a time. Such errors might, in a measure, balance each other, but Fiedler's⁴ figures, whose original paper I have not seen, are so one-sided that he would seem to have included cases in which the effusion occurred in an already well-established tuberculosis of the lung. A striking point in these statistics is the wide variation in the experience of the various observers. Blakiston reports 53 cases which had remained well for several years. Austin Flint, 47 cases with three possible instances of subsequent tuberculosis; out of 21 cases reported by J. P. Bramwell,⁵ three only died of tubercular disease. Corriveau⁶ had but four deaths from this cause out of 27 cases, one of whom he had followed twenty-five years and one fifteen. On the other hand, V. Y. Bowditch⁷ found in 90 cases occurring between 1849 and 1879, that 32 had become consumptive. Barr,⁸ out of 57 cases occurring between 1880 and 1884, found that 21 at the time of his report (1890) had already died of pleurisy or some well-recognized tubercular disease, mainly phthisis, and of 44 cases treated by Böcher, 32 presented later manifest symptoms of tuberculosis of the lungs. Fiedler, quoted by Sée, says that of 112 cases of pleurisy treated by thoracentesis, but 21 recovered; of the 91 other patients, 25 died of phthisis either at the hospital or their homes; 66 recovered from the pleurisy, but were found later to be victims of confirmed phthisis or other tubercular disease.

Four hundred and fifty-one cases are here mentioned of which 176, or about 39 per cent., developed phthisis or other well-marked tubercular affection. Coustan and Dubrulle,⁹ from their army experience, say that all soldiers who have suffered from pleurisy are no longer fit for military duty and that a majority die later of consumption. An exactly opposite opinion is held by Blachez who mentions an epidemic of pleurisy many years ago without the subsequent development of pulmonary disease in a single case. Westbrook, Vickery, and others have reported cases which were followed by phthisis and from a review of the recent literature there seems to be an increasing tendency to ascribe to the tubercle bacillus a more and more important rôle in the causation of pleural effusions, but as the pendulum of medical opinion is proverbial for the length of its vibrations, it is fair to ask if, in the present instance, it is not tending to swing too far in this direction. The frequent occurrence of pleurisy as a complication of pneumonia, rheumatism, measles and other infectious diseases where no doubt exists that it is the same in origin, suggests the question, if so-called idiopathic pleurisy may not at times be due to the same causes,

which for some reason affect only the pleura, a question which the discovery of the pneumococcus in pleural effusions, not secondary to pneumonia, goes far toward answering, while the reported curative effect of salicylic acid in many cases suggests its being at times a local manifestation of rheumatism. From any series of cases similar to that given above, a certain number must be deducted for those who would have developed phthisis in the natural order of events without the incidence of a previous pleurisy, while the part which a latent tuberculosis of the bronchial lymph glands may take in the subsequent onset of a more general process must also be considered, as has recently been emphasized in papers by H. P. Loomis¹⁰ and Northrup.¹¹ Of 91 autopsies on tubercular patients collected by the latter from the records of the New York Foundling Asylum in which conclusions could be drawn as to the primary seat of the lesion, in 88 it was situated in the bronchial glands, which in nine cases had already advanced to a state of cheesy degeneration while the lungs showed only a beginning tuberculosis. In 13 cases, most of which had died from acute infectious diseases, they were alone affected. Loomis inoculated rabbits with material from the bronchial glands of 30 adults who had died either suddenly or after an acute disease and found that in eight cases active tubercle bacilli were present, although there were no other traces of tuberculosis. There can be no doubt that the unfortunate possessors of such glands are constantly exposed to the dangers of a general infection which may occur whenever proper conditions are found for dislodging the bacilli and setting them adrift in the general or pulmonary circulation. Such conditions would seem to be well satisfied in acute pleurisy with effusion where a shower of bacilli might be washed out by the large amount of fluid which, in process of absorption, must pass in part, at least, through the lymphatics. Ulceration of the degenerated glands might also be set up by the sudden increase in their functional activity. Such a theory would explain the onset of a general miliary tuberculosis following the rapid absorption of an effusion as in the cases reported by Litten, Troisier and others. In other cases where months may pass before phthisis is recognized, it is possible that the dislodged bacilli may remain quiescent or develop so slowly as to cause no special symptoms until some further impulse is given.

In conclusion it can be said that a very considerable proportion of cases of acute, apparently idiopathic pleurisy with effusion, is followed by pulmonary phthisis. In a part of such cases the pleurisy is doubtless of tubercular origin and is its earliest expression just as hemorrhage may be the first symptom and not the occasion of pulmonary phthisis, while of the cases which remain permanently well, in view of the spontaneous recovery of tuberculosis in other situations, it is fair to assume that a certain proportion is due to the same cause, the process remaining local. In others, though itself benign, pleurisy may be the cause of grave disease by dislodging the bacilli from their comparatively harmless position in the bronchial glands, or by crippling the movements of the lung favor the development of phthisis. Whatever may be the relative importance of these processes in inducing the same result, the deductions to be drawn as to treatment are sufficiently obvious and should lead to the

greatest care during convalescence to protect the patient so far as possible from danger by building up his powers of resistance, while the expansion of the lung should be aided by early, and if necessary, repeated aspiration. Equally obvious, for both prognosis and treatment, is the necessity for frequent, careful examination of the lungs themselves as well as a bacillary examination of the sputum, lest in the greater interest of watching the daily changes of the fluid the beginning of a more serious condition may be overlooked.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

G. G. SEARS, M.D., SECRETARY.

REGULAR Meeting, Monday, December 28, 1891, the President, DR. FREDERICK I. KNIGHT, in the chair.

DR. C. M. GREEN read a paper on

THE CARE OF PREGNANT AND PUERPERAL WOMEN.¹

DR. REYNOLDS: I am very glad to hear this paper. I think the subject is one of the very greatest importance. I think it a very widespread belief that the sole duty of the obstetrician is confined to labor. I think myself that, in the great majority of cases, among the women of more delicate health of the upper classes of society, the care of pregnancy and the puerperium is, by all odds, the most important part of the obstetrician's duty, and has more to do with the after-health of the patient than anything he can do in ordinary labor, with the single exception of asepsis.

I think there is one thing that the physician in pregnancy should bear carefully in mind and that is the extent to which the normal annoyances of pregnancy are to be exaggerated by mental influences. It is very important that he should always bear in mind the fact that by too much attention, by appearing to attach too much importance to minor troubles, he may bring the patient to a state in which she imperatively demands treatment for things she had better endure. While he should bear that in mind carefully, and while it is often a difficult point to decide whether a given annoyance should be endured or be treated, I do think that the decision of this point properly and the treatment of the annoyances from the moment that they exceed the physiological limit conduces enormously to the health of the patient in succeeding years.

As regards the treatment of nausea and vomiting during pregnancy I have been especially impressed with the truth of what Dr. Green said about the importance of having something to eat before the patient rises from bed. I believe that the reason why the nausea of pregnancy is known as "morning sickness" is because that is the only time in the twenty-four hours that the patient has been twelve hours without food, and I think that, in the vast majority of cases if at the time when nausea first appears the patient takes a hearty supper just before she goes to bed, and a cup of milk before she rises in the morning, the nausea will be very mild even in cases where it might become severe without that precaution.

¹⁰ New York Medical Record, December 29, 1890.

¹¹ New York Medical Journal, February 21, 1891.

¹ See page 186 of the Journal.

Constipation is certainly one of the most important of all the derangements of pregnancy. I think nothing conduces more to comfort during the later months of pregnancy and prompt recovery after labor, than early treatment of constipation. If constipation is allowed to persist to the sixth, seventh or eighth month, very little can be done for it except the employment of cathartics, often in considerable doses and for long periods, and that use of cathartics, it seems to me, hardly relieves the system fairly. It prevents the worst effects of the accumulation of feces, but defecation can seldom at that period, with the fetus and uterus pressing upon the intestines, be made sufficiently regular and normal and physiological to relieve the patient from the evils which attend the minor degrees of constipation in ordinary health if an accumulation of feces has already been permitted to occur. I differ from Dr. Green a little in what I understood to be his advice in the employment of enemata. I believe it is a mistake to have the patient contract the habit of making frequent use of enemata, and I have failed to find that attention to diet will regulate the bowels. I have been rather accustomed to pin my faith to the fluid extract of cascara sagrada or the elixir rhamnus Pursh, Co., (N. F.) If the patient begins the use of one of these preparations, using them three times a day from early in the pregnancy, and carries it through to the end, I think the bowels almost always maintain a fairly normal action.

Another point of great importance is care to recommend the abundant use of water during the pregnancy. Nothing, I am convinced, adds more to the safety of the patient than that the physician should be careful to see that she takes a sufficient quantity of fluid of some kind; and I think that as Dr. Green has stated, most women so uniformly take too little water, that this is a point to speak of in almost every case.

As regards the mental condition of the patient, every one knows the delight which women who have had children have in detailing to primiparae the sufferings of labor. I think a point of great importance in the care of the latter months of pregnancy is for the physician to take care to draw his patient out, find out her ideas about labor, contradict some of these stories, and reassure her. I think this often has more effect on the *morale* of a patient, and on her general condition, than is ordinarily imagined. I think it is important to look after the nervous tone of the patient, to care for her sleep, to caution her to avoid anxiety, worry and mental work.

As regards pelvimetry, I agree with Dr. Green that the employment of pelvimetry in the ordinary run of cases is not only impossible, but entirely unnecessary from the obstetric point of view, for the reasons he gave. I think it is important to urge upon physicians to reach for the promontory of the sacrum at the first examination in every case of labor. If there is any contraction of the pelvis it will be detected then, and any degree that is so slight as to have escaped attention during pregnancy will thus be recognized at the beginning of labor, which is plenty soon enough to recognize minor degrees, and will prevent their neglect until serious complications have arisen.

I was a little surprised to hear what Dr. Green said about the care of inverted nipples. I should be afraid to habitually pull out inverted nipples for fear of reflex action upon the uterus.

DR. A. H. NICHOLS: While not venturing to add

anything to the subject of this paper, I can perhaps furnish another illustration of the physiological principle that while the danger of abortion from external violence is comparatively small during the greater part of the month, there does exist a very marked susceptibility to such an accident during or immediately before the menstrual epoch. I remember when a student in Paris to have been impressed by a seemingly exaggerated statement on this point made by Professor Depaut, that a pregnant woman could under ordinary circumstances jump from a second-story window with greater safety as regards an abortion, than she could slip from an edge-stone at this particular time of the month, when the reproductive organs are more easily excitable. An experience derived from more than twenty summers spent at a sea-side resort has convinced me that there exists a very imperfect knowledge of this law on the part of many physicians sending thither women patients; for pregnant women are, as a rule, not furnished with instructions as to the propriety of bathing in the ocean where very considerable shock may be sustained from the low temperature of the water or from the height of the waves. When consulted upon this matter, my advice has invariably been, that if the woman is otherwise in good health and the abdominal enlargement not extreme, sea-bathing can be indulged in with benefit under the simple restriction with regard to the menstrual epoch, as above indicated: and in no instance have I observed any ill-effects from such bathing where this rule was observed. On the other hand, I have witnessed several abortions and many threatened abortions in women who have subjected themselves to the violence of the surf indiscreetly and in violation of this rule. I am furthermore inclined to the belief that a more general application of the principle embodied in this law would permit much greater latitude to women in the way of general exercise, gymnastics, etc., than is now accorded; and it would certainly seem that the improved physical status thus induced would tend to facilitate the process of childbirth.

DR. H. W. BROUGHTON: I feel glad that my own habits seem to be so well in accord with the teachings of so good a teacher as Dr. Green. A case by way of illustration, as Dr. Nichols has set the example of practical experience, is suggested to my mind that shows the value of encouraging our patients to call upon us in the early months of pregnancy. Not long ago a woman called upon me with a view of consulting me about her little girl. I was impressed immediately with the pallor and extreme whiteness of her face, and asked her as to the occasion of it. I learned that she was three months' pregnant, and that led me to ask further questions. I found she was limiting her self to a strictly vegetable diet. I asked why that was done; and it seems she had read with great interest a book something after the general style of "Childbirth Made Easy," written by some very wise person who imagined that by an absolute vegetable diet the bones would be so softened that the fetal head would pass without pain. I found my patient was deeply imbued with the idea. She was a very intelligent woman. I saw that some tact would be necessary to disabuse her mind of the fallacy, and I ventured to remind her that a diet that would produce so marked an effect upon her own system as to soften the bones might produce a very serious effect upon the child. She would not want a child to have bones so soft as to be bow-legged,

and that idea seemed to take her. She went home, changed her diet, and in a few weeks she was in a very much better condition.

In regard to exercise. I should agree fully with Dr. Green as to the desirability of exercise, but the matter of gymnastic exercise has seemed to me to require careful instructions and caution on our part. I do not know whether there is any foundation to the popular notion that reaching the hands above the head is likely to cause the cord to encircle the neck. I should like to ask Dr. Green his opinion upon that point. In a general way I think gymnastic exercises should be somewhat restricted, to say the least.

There is one other matter which is perhaps trivial, and yet has been observed in the history of the Roman empire. It was the custom among the wealthy Romans to surround their pregnant wives with the most beautiful pictures and statuary so that the mother might be likely to produce beautiful offspring. I question how much direct influence such habits would have, and yet I think it would be well for a mother to accustom herself to viewing those things which are beautiful and which delight her mind to the end that the child may be comely. I know of many women who habitually during the months of pregnancy make it a point to look at pretty babies and at pretty little children and study to surround themselves with such things as appeal to their eye. I am not sure that it is an unpractical thought.

In the latter months of pregnancy iron is usually prescribed. I have been apt to use the German preparation as being less constipating.

With regard to the nipples, I have not observed any bad results from the custom of using the hot bottle, but have invariably instructed the patient to draw the nipple out with her fingers, and apply an astringent lotion, as Dr. Green suggests.

DR. C. W. TOWNSEND: My attention has been forcibly called recently to the importance of examining the urine. I think most of the cases of eclampsia are in women who have not been seen at all before the time of the eclampsia or until the immediate symptoms of eclampsia came on. I saw a patient of that sort the other night and it seemed to me if this patient had been seen a month before and the urine examined and proper treatment instituted the eclampsia could have been prevented, and the patient could have gone on to full term instead of requiring manual dilatation and version at the seventh month.

DR. H. F. VICKERY: I came with great interest to hear Dr. Green's paper, and was disappointed he did not have time to speak of the period after delivery. I hope he will in the second volume.

What Dr. Townsend just said reminds me of a most impressive incident. A physician was engaged by a bride to attend her in her confinement, and she was very anxious that he should not come near the house until pregnancy ended. When he was sent for, she was dying of eclampsia from renal trouble. It is a case which he regretted very much, although it was not his fault at all.

It seems to me that where albumen is found in many cases, it is not of any significance, because it is not associated with renal inflammation. I should always search for casts. In those cases where I have found casts I have always had trouble so far as I recollect now. I think, beside the other ways of determining whether there was danger, the microscope should be used.

I have just been obliged to draw the water of a woman recently delivered, for a week, and I read a suggestion this morning which dropped into a thirsty mind. I do not know whether any other gentleman has tried it; but this writer suggested that for some time before delivery a pregnant woman should be requested to practise making water on the bed-pans. I shall certainly request my nurses to ask their patients to do it. I would like to ask Dr. Green if he has had any experience about that.

DR. O. K. NEWELL: I have listened to this paper with great interest. It seems to me there is one important point in the management of pregnant women, and that is the determination by care and treatment of one kind or another whether or not the mother will be able to nurse her children. One outcome of civilization seems to be that women living under its influences tend to lose the ability to nurse children. Whether that is due to one cause or another is not for me to say; but it seems to me it is one very important aspect of child-bearing in this day and generation.

DR. J. C. MUNRO: Dr. Green spoke of giving Quevenne's iron. I think it may not be generally known that when Quevenne's iron is written for, the druggists are liable to give some inferior substitute, which is not so easily absorbed. In pregnancy and other conditions it is even more easily assimilated by combining with Vallet's mass. In the matter of cathartics Dr. Reynolds spoke of a number of the buckthorn bark preparations. I have used pretty steadily for three years the rhamnus frangula bark. Patients chew and swallow a piece of the bark as big as the finger-nail three or four times a day, gradually diminishing the dose. It is more efficacious than any cathartic preparation I have ever seen, especially among pregnant women or those chronically constipated. It is a drug not much used, because it is not expensive and not fashionable; but if physicians are careful to get the pure bark I think they will find it more useful than any preparation.

DR. GREEN: In regard to the preparatory treatment of flat or inverted nipples, I have never known harm to follow the careful use of the hot bottle. I doubt if the reflex irritation is sufficient to excite uterine contractions.

As regards the mental and nervous condition of pregnant women, it is of course important that in our efforts to guide women into ways of hygienic living we should not make them unduly mindful of trivial ailments nor excite their nervous apprehensions. My effort is to take the woman's mind entirely away from her pregnancy. To this end I advise against reading books which treat of pregnancy and labor; I inform patients, as far as is found necessary, of such things as it is well for them to know, and only ask them to follow the laws of correct living, and then notify me if anything goes wrong with them.

The practice suggested by Dr. Vickery of training women to pass their urine lying on their back was originally proposed by Skutsch. I have never followed this plan, and doubt the wisdom of it. It is well to remember that some women, who cannot pass water lying on their back, can do so by resting on the hands and knees. Most women in the lower classes sit up on a chamber-vessel to urinate, and in spite of tradition to the contrary, I am not sure that such a procedure is harmful, unless there is much weakness, a torn perineum, or organic disease of the heart.

DR. G. G. SEARS read a paper on
THE ETIOLOGY OF ACUTE PLEURAL EFFUSIONS.²

DR. F. MINOT: I should agree with the reader as to the necessity for making careful observation of a patient with acute pleurisy for a long time afterward; but I think the question of the effect of simple pleurisy in producing pulmonary tuberculosis at a later period is one that it is almost impossible to determine at the present time, since tuberculosis of the lung is the most frequent of all diseases, causing about one-seventh of all deaths. There is no question, of course, that a very large number of cases of acute pleurisy recover completely, the patient living a long time, and never showing symptoms of tuberculosis. The frequency of pulmonary tuberculosis makes it very possible that a former pleuritic patient should be attacked with it, as well as anybody else; but I do not think the true connection between the two is so far established by statistics as to make it very probable. Undoubtedly there are some cases in which pleurisy with effusion is primarily tuberculous. In other cases the patients may have had latent pulmonary tuberculosis, and a small tubercular cavity might break into the pleural cavity, and the bacilli gain admission in that way; in others, through the lymphatics or blood-vessels. A practical point is the importance of early aspiration of the chest in all cases of serous effusion, on the bare supposition that the pressure upon the lung might develop the disease latent there in the lymphatic glands.

DR. VICKERY: I have been much interested in this paper, and I have little to add. There is one thing,—a lung which has been allowed to retrace by the presence of a large effusion is not favored with such iteration as in normal circumstances, and affords a good nidus for any bacilli that come along. I suppose we all breathe tubercle bacilli more or less into our lungs, and they are overcome there by the cells; and in the disabled lung the danger is greater than in the healthy lung. So, whatever our views may be as to this yet unsettled point, there can be no question in my mind that the care of a person who has had acute pleurisy with effusion should be very great in hygienic measures to protect him against tuberculosis. A good many of those gentlemen who have seen favorable results follow acute pleurisy have patients in such circles of society with so much intelligence and wealth that they are more apt to get well even if they have tuberculosis. I think that is one reason why Dr. H. I. Bowditch entertained so favorable a view of pleurisy with effusion, and why a good many country doctors are very much surprised that there is any such discussion going on. Their cases are in the open air, and one or two bacilli do not make much difference. The tissues and the oxygen in the air overcome them.

DR. H. JACKSON: I think it is a most difficult matter to prove one way or the other, but clinically it seems to me very difficult to believe that ordinary simple pleuritic effusion is due to the invasion of tubercle bacilli. Tuberculosis of the pleura and of the peritoneum is not very rare, and when it does exist there is some anatomical lesion of the surface. Most authorities consider bloody effusion usually points to the presence of tuberculosis as a cause; also, as seen in the lower animals, miliary tuberculosis of the peritoneal cavity is very apt to cause a slightly bloody fluid, and the pleura is thickly studded with military

tubercles. I think, if we assume that tuberculosis is the cause of ordinary pleurisy, we must at the same time assume that it causes that effusion without giving rise to any anatomical lesions of tuberculosis, that is, to the presence of miliary tubercles or of new formed tissue. That, I myself am not prepared to believe. I do not believe tubercle bacilli will cause effusion without some anatomical lesion in the pleural surface.

DR. VICKERY: I think that tubercle bacilli have been seen in the false membranes following pleurisy with effusion, on section. Perhaps it is just chance that they were there.

DR. JACKSON: I did not know of their being found in that particular way.

DR. F. I. KNIGHT: There seems to be a general feeling of uncertainty in regard to the matter, in which I share. It is one of those questions which I feel is still under judgment. Certainly I have seen a good many cases of complete recovery from pleuritic effusion, and I have also seen a good many cases where I could not but feel that the invasion of bacilli and subsequent disease was induced by the crippled condition of lung by long exposure to pressure, and I should certainly like to emphasize the point Dr. Minot has made, that that is one great reason for early interference. If the effusion remains any great length of time, more than four or five weeks, we almost never see complete recovery. There is a decided want of expansion left, which seems to me to be always an invitation, as it were, to other pathological processes.

ALBERT N. BLODGETT, M.D., SECRETARY.

REGULAR meeting, December 16, 1891.

DR. V. Y. BOWDITCH read a paper on

THE ESTABLISHMENT OF SANITARIUM FOR PULMONARY CASES IN THE IMMEDIATE VICINITY OF OUR GREAT CITIES.¹

DR. MASON: I am sure that Dr. Bowditch's sanitarium will be of the greatest possible service, especially when its scope is increased through larger means, so that more patients can be received, and when it can be made available for men. At present there is the greatest difficulty in Boston in having a male phthisical subject in the early stages taken care of for a long time. They come to our out-patient departments and wards for a few weeks and then disappear. They are not able to pay a large amount of money for their support, therefore they generally go rapidly from bad to worse. The women have a better chance in small homes for that purpose. I do not think a large number recover in the small city establishments. I hope the time will not be long before Dr. Bowditch's sanitarium will be able to receive at least a few men such as present themselves every week at our hospitals and have to be turned away without much hope of benefit.

DR. OSGOOD: One factor of Dr. Bowditch's sanitarium, which I am very glad has been opened, I wish to endorse strongly, and that is the separation of his

² See page 192 of the Journal.

¹ See page 150 of the Journal.

patients. This plan recalls to me an interesting visit which I made ten or twelve years ago at the Hospital for Consumptives in Ventnor, Isle of Wight. For, at this institution, consumption was treated upon what was called, the "separate system." At the time this hospital was opened the bacillus of consumption, of course, was unknown, and undoubtedly the separate plan of treatment adopted resulted simply from the observation of physicians, namely, that consumption, if not contagious, presented a good many strange coincidences in cases where persons who took care of the consumptives themselves were attacked by the disease. However that may be, the Ventnor plan, so far as I know, was in advance of any treatment of consumption that is in general use to-day, and I would like to ask Dr. Bowditch if his sanitarium is not the only one in the country in which patients are treated on the separate system, which, of course, is the only one to be used in this disease.

DR. BOWDITCH: I cannot say positively. I know of Dr. Trudeau's sanitarium at Saranac. He never has more than two patients in a room, and most of them have separate sleeping apartments.

DR. OSGOOD: In the Ventnor Hospital, by means of charitable donations, every patient, even the poorest, has his private room. I am quite able to sympathize with Dr. Bowditch's new project, because, being connected with the Home for Incurables, I am fairly pestered by people who demand entrance for consumptives into the Home. Our regulations refuse admission to such cases. It seems to me there is no question as to the great need of such retreats for consumptives among the poor and I hope Dr. Bowditch's sanitarium will become rapidly enlarged.

DR. KNIGHT: I think there can be no question in the mind of any one who has had to deal with pulmonary disease, tuberculosis particularly, that it is one that requires such constant care and supervision that it can be afforded much better in an institution than out of it, it being not the disease which has to be treated at present, but the condition of the patient, and the factors are so many which have to be regarded in improving the condition of the patient and enabling him to withstand the disease and bring about its ultimate arrest, that it is only the most constant care which brings about in the majority of cases the successful result, and there is no question that the results are better in sanitaria than outside of them. Of course the sanitaria in health-resorts like Colorado are going to show better results as a rule. There are two in Colorado Springs and it is fair to suppose that their results are going to be somewhat better at any rate than sanitaria in our own neighborhood, but the constant care which they get in the sanitaria here is going to be productive of excellent results.

The first time that this subject was brought to my mind very forcibly that hospital treatment was good for consumption was when I was in Bellevue temporarily serving with the elder Flint. He said one day "Did you ever notice how well these consumptives do in the hospital although our diet is poor and you would suppose in the crowded condition of our wards that they would not do particularly well, but you notice how well they are doing, and they are not having any medicine. You see what the regulation of their life will do for them?" This was true, so far that the majority of consumptives who came in all stages, improved from the judicious regulation of their

diet and habits of life. Now it is perfectly well known that a patient will undo in one day's over-exercise, all that you have done for him in six months. That is not likely to happen in the sanitarium, neither are they likely to be upset in the thousand and one ways that their relatives and friends at home offer them. That is one advantage, being free from the constant meddling and annoyance of friends.

Then the association of patients with the same disease curiously enough leads them to feel very differently in regard to it. They talk over their symptoms, expectoration, consolidation and bacilli just as we talk about matters of medicine, with no more feeling really than we have.

The other day when I was at Sharon, I was asked to drive down to the station with an attractive young lady. She had been discharged at the end of a week's residence. She was supposed to have serious disease, but upon careful examination it was found that she did not have tubercular disease at all. I imagined she would rejoice at getting away from all those people, but, on the other hand, she was mourning that she could not stay. She said it was a delightful place and she would like to have staid several months, so that the impression made on her mind in a week's time was only a pleasant one.

DR. BOWDITCH, in closing, stated the present capacity of his sanitarium was for nine women. Incipient cases were especially desired, since they offered better prospects of cure. It was not a hospital. All the patients were up and about and able to take walks. They were not obliged to lie in bed unless something occurred which made it desirable to remain in bed for a day or two. There was no provision for free patients at present. The price of board for each patient was five dollars per week.

Recent Literature.

Manual of Chemistry. By W. SIMON, Ph.D., M.D., Professor of Chemistry and Toxicology in the College of Physicians and Surgeons. Third edition, thoroughly revised. With forty-four illustrations and seven colored plates. Philadelphia: Lea Brothers & Co. 1891.

An earlier edition of this manual has been reviewed in these columns, and it is unnecessary therefore to give this one an extended notice. The book has been prepared specially for the use of students of medicine and pharmacy, and includes descriptive chemistry, qualitative analysis, and physiological chemistry. It is, of course, impossible to do full justice to these three branches of chemistry in a book of the size of this one and it is not surprising that many subjects have failed to receive, at the hands of the author, the attention that their importance demands. In spite, however, of some deficiencies of this kind the book is better than many of the works on chemistry which have been thrown upon the world during the past few years, and will doubtless be found useful in connection with lectures and laboratory demonstrations covering the same ground. As a text-book or book of reference for students in general, we do not see that it supplies any present want.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, FEBRUARY 25, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

these results are quantitative and simply show the absorption of very minute quantities of the iodide and it is still difficult for any one but a therapeutic enthusiast to look with much favor upon this kind of medication, so far as the action of the drug itself is concerned.

The article of Peters led Paschkis and Obermayer¹ to publish a brief statement of some positive results obtained by them. They used the oleate of lithium made into an ointment with lanolin. This metal was chosen on account of the ease with which small quantities may be detected by the spectroscope. The ointment was rubbed into the skin of the back of one of the experimenters on two occasions and once a hairless African dog was exposed to the spray of a five per cent. solution of the chloride of the same metal. In each of these cases lithium could be detected in the urine, but the quantity was exceedingly small, enough so to make any therapist sceptical.

ABSORPTION OF DRUGS BY THE SKIN.

THE old question of the absorption of drugs through an intact epidermis has been revived by Peters¹ who seems to have thrown a new light upon the subject. Almost all carefully conducted experiments (for example, Röhrlig, 1872, Fleischer, 1877, Yuhl, 1884, Riker, 1886) have shown that when ointments containing potassium iodide are rubbed into a sound skin, none of the KI is absorbed. This drug has been usually selected, not on account of its harmlessness, but chiefly because of the ease with which very small amounts may be detected in the secretions. When any iodine was found in the urine, as did sometimes occur, it was thought, in view of its infrequency, that an absorption had occurred by means of a mucous membrane (vapors of the material used) or that a skin abrasion had been overlooked. Rózsahegyi,² on the other hand, had maintained that the skin could absorb small amounts of the iodide, but believed the amount too small to be of therapeutic significance. He also pointed out that for the detection of small quantities of iodine, the liquids in question should be evaporated and then carefully extracted with alcohol and ether, and also that CS₂ was a better reagent than starch or chloroform for iodine which should be set free by a mixture of strong nitric and sulphuric acids.

Peters made use of Rózsahegyi's method (with some modifications) and finds the CS₂ reaction of such delicacy that he can detect iodine in a KI solution of 1:80,000. He found that when fresh ointments, of varying composition as to fat, but all containing KI, were used, a very small amount of I could be detected after a few hours in the urine when properly examined, even though the liquid, before evaporation, gave negative results. The failure of other observers in similar experiments is thought to be due to the imperfection of their method, although that has usually been one which had met with general approval. None of

TYPHUS FEVER IN NEW YORK.

DURING the past week typhus fever cases have continued to develop among the Russian Hebrews who came over on the *Massilia*, but with the possible exception of a supposed case of the disease in an Italian, received at Bellevue Hospital, none have occurred outside of these Russian immigrants.

During the past week three deaths have occurred from typhus fever. One new case was reported on February 18th, and four on the 19th. Several cases have also been reported among the Russian passengers who had gone to other places before the disease was discovered by the Board of Health, among them being cases at Valatie, Columbia County, N. Y., and at North Oxford and Oakdale, Mass.

The number of deaths that have occurred from typhus fever in New York since 1865 is as follows:

1866	1	132	1878	1	4
1867	1	19	1879	1	4
1868	1	137	1880	1	3
1869	1	125	1881	1	160
1870	1	96	1882	1	17
1871	1	65	1883	1	15
1872	1	86	1884	1	27
1873	1	39	1885	1	15
1874	1	14	1886	1	14
1875	1	28	1887	1	9
1876	1	29	1888	1	4
1877	1	17			

Since 1888 there have been no deaths from the disease until now.

In order to stamp out typhus fever as promptly as possible in the city, the New York Board of Health has appointed ten special sanitary inspectors, selected from the physicians of New York, whose duty it shall be to make a house-to-house visitation of all tenement and lodging houses, in order to discover any cases that may hitherto have escaped the notice of the authorities. For this purpose the city has been divided into ten districts, and each inspector is required to visit every house in his district and personally examine all its inmates. He is also instructed to make a thorough search

³ H. Paschkis and F. Obermayer: Weitere Beiträge zur Hautresorption. Centralbl. f. Klin. Med., 1891, 65.

for small-pox cases, and is provided with virus to vaccinate all persons who are willing to have this done. Cases of small-pox are being discovered every day in the city, and thus far forty-one cases have been reported during the present month; a very unusual number.

ANNUAL APPROPRIATIONS FOR HOSPITALS IN BOSTON, OTHER THAN THE CITY HOS- PITAL.

THE Committee on Cities of the Massachusetts Legislature gave a hearing on Wednesday last, on the question of allowing the City of Boston to give annual appropriations to hospitals other than the City Hospital. A large number of citizens representing different interests appeared against the bill. The only person appearing for it was the member who first introduced the measure in the Common Council, but his advocacy seemed half-hearted and as if chilled by his surroundings, and when he realized his solitary position he readily acquiesced in the proposition to report, inexpedient to legislate.

We are really amazed that any one should have had the temerity to go to the legislature or anywhere else with a proposition so pregnant with possible mischief.

◆◆◆

MEDICAL NOTES.

RANDALL'S ISLAND HOSPITALS. — The New York Commissioners of Public Charities and Correction have appointed William James Morton, M.D., neurologist to the Randall's Island Hospitals.

IMMIGRATION AND TYPHUS. — A resolution has been introduced in the national House of Representatives in concurrence with the Senate providing for an investigation by the Senate and House Committees on Immigration, of the law relative to immigration, and the facts attending the condition of the typhus-stricken Russians at New York.

REMOVAL OF FILTH AT QUARANTINE. — Since the outbreak of typhus fever in New York, the quarantine officers in Boston have devoted especial attention to Russian Jews. Nine from the steamer *Norseman* and forty from the *Huron* were removed to the quarantine station, and were compelled to take a bath and remain until their clothes were thoroughly cleaned. An account of their first impressions of America would be interesting.

AN INTERNATIONAL CONGRESS OF GYNECOLOGY AND OBSTETRICS. — The Belgian Society of Gynaecology and Obstetrics has taken the initiative in the organization of a series of International Congresses to be held every four years in Switzerland and Belgium alternately. The first Congress is announced to take place at Brussels between the 14th and 19th September, 1892. Three main questions are set down for discussion — (1) Pelvic Suppuration, by Dr. Segond (Paris); (2) Extra-Uterine Gestations, by Dr. Martin

(Berlin); (3) On Placenta Praevia, by Dr. Berry Hart (Edinburgh). The Secretary-General is Dr. Jacobs, of Brussels.

CHOLERA AMONG THE PILGRIMS TO MECCA. — According to the Egyptian delegate to the Hedjaz, Dr. Saleh Soubby, there were in 1891, 46,953 pilgrims who came by sea on their pilgrimage. Of these, 25,253 returned to their homes, the remainder, 21,700 having died, most of them with cholera. Of the large number journeying entirely by land the mortality can only be estimated.

FAMINE IN INDIA. — Official notice has been given in Bombay that famine prevails in that Presidency, and that the famine code will be applied over an area of 6,000 square miles, including the districts of Bijapur, Belgaum and Dharwar. These districts contain a population of 1,500,000 persons.

CALOMEL AND MORPHINE. — During the last year and a half five deaths have occurred in Prussia by the dispensing of morphine by mistake for calomel. On this account the Prussian government has decreed that in future morphine and its salts must be kept by apothecaries in distinctive cupboards, and it is forbidden to prepare mixtures in which either morphine or calomel is used in powder until needed to fill a prescription.

BOSTON.

BEQUESTS TO INSTITUTIONS. — By the will of the late Richard D. Rogers, the sum of \$10,000 is bequeathed to the House of the Good Samaritan.

BOSTON BOARD OF HEALTH. — The Board of Aldermen have confirmed E. J. Donovan as a member of the Board of Health for three years, and for the unexpired term of E. L. Pillsbury, resigned.

DEATHS IN BOSTON. — During the past week there were 206 deaths reported, against 184 for the corresponding week last year, making the death-rate 23.3. The deaths reported as due to influenza were four, consumption 22, pneumonia 27, bronchitis 15. Persons over sixty years of age, 42.

AN ELEVATED ROAD THROUGH HOSPITAL GROUNDS. — A proposed elevated road in the west end of the city, which was to go through the property of Massachusetts General, the Lying-in, and the Samaritan hospitals and the West End Nursery was last week vigorously opposed by representatives of these institutions before the Rapid Transit Commission.

NEW YORK.

INFLUENZA seems to have revived to some extent, as on February 18th, seven deaths were reported from it; the largest number since February 3d, when there were eight deaths.

INVESTIGATION OF A "KEELEY INSTITUTE." — A resolution introduced into the State Senate to investigate the treatment at the Keeley Institute at White Plains, has been referred to the Committee on Public Health.

THE RAPID BREATHER.—The physicians who examined Michael McCarthy, the patient whose extraordinary rapidity of respiration was supposed to be due to a lesion of the medulla oblongata, at Bellevue recently, have been not a little astonished within the last few days to learn that his apparently incurable malady has suddenly disappeared. This was brought about, it seems, by a visit to Father Adams, a suspended Roman Catholic priest of Brooklyn, who professes to cure disease by the application of certain holy relics in his possession. It would appear, therefore, that the case was really one of hysteria, or, at all events, of functional character, and that the impression made on him by the priest and his relics was sufficient to remove the difficulty, at least for the time being. It is said that the man received \$4,000 damages from the Boston Electric Car Company, on account of the result of the injuries he received. Since publicity has been given to this "miraculous cure" by the newspapers, the reverend father has been fairly besieged by hosts of sufferers of various kinds, the lame, the halt and the blind.

SUIT AGAINST A HOSPITAL.—A case of considerable interest has been in the courts during the past week. Suit was brought for \$50,000 damages against the New York Hospital for the loss of a boy's leg which, it was claimed, was due to incompetence and negligence on the part of the hospital surgeons and nurses. The judge finally dismissed the case on the ground thatasmuch as the New York Hospital was a charitable corporation, a suit, under the laws of the State, could not be sustained against it.

Miscellan.

EXECUTION BY ELECTRICITY.

At a meeting of the Section on Public Health and State Medicine of the New York Academy of Medicine, February 17th, Dr. Ira Van Gieson, who made the autopsy, with microscopic examinations, on the body of Kemmler, the murderer, executed by electricity at Auburn prison, gave a report of the results of his examination. He described the appearances of the various parts of the body in detail, and asserted that in such executions, beyond the blistering of the skin by the electrodes, the current passes through the body without producing any effect upon the organs or internal tissues. The blood corpuscles, red and white, he declared, were not affected either by rupture or contraction or in any other manner by the passage of the current.

Dr. Samuel Lockwood, of Freehold, N. J., however, in a paper read before the New York Microscopical Society, on February 19th, on "The Blood of Kemmler after His Electrocution, Demonstrating the Effect of Electric Shock on the Blood Corpuscles," stated that there were certain changes produced in the blood. He examined two specimens of Kemmler's blood—one taken from the back of the head, near the place of contact of the electrode, and the other from the thigh, where the blood was not in the direct line of the current, and was only affected by the general diffusion of

the electricity through the body. He found that the corpuscles were both smaller and fewer in number in the blood from the head than in that from the thigh. The contraction in size, he believed, however, was due to the heat produced by the current.

BIRDS AS SURGEONS.

SOME interesting observations relating to the surgical treatment of wounds by birds were recently brought by M. Fabio before the Physical Society of Geneva.¹ The author quotes the case of the snipe, which he had often observed engaged in repairing damages. With its beak and feathers it makes a very creditable dressing, applying plasters to the bleeding wounds, and even securing a broken limb by means of a stout ligature. On one occasion he killed a snipe which had on its chest a large dressing composed of down, taken from other parts of the body and securely fixed to the wound by the coagulated blood. Twice he had brought home snipe with interwoven feathers strapped on to the sides of fractures of one or other limb. The most interesting example was that of a snipe, both of whose legs he had unfortunately broken by a misdirected shot. He recovered the animal only on the following day, and he then found that the poor bird had contrived to apply dressings and a sort of splint to both limbs. In carrying out this operation some feathers had become entangled around the beak, and not being able to use its claws to get rid of them, it was almost dead from hunger when discovered. In a case recorded by M. Magner, a snipe which was observed to fly away with a broken leg, was subsequently found to have forced the fragments into a parallel position, the upper fragmants reaching to the knee, and secured them there by means of a strong band of feathers and moss intermingled. The observers were particularly struck by the application of a ligature of a kind of flat-leaved grass wound round the limb, of a spiral form, and fixed by means of a sort of glue.

INFLUENCE OF COLD ON THE PRODUCTION OF PNEUMONIA.

LIPARI,² in a paper on the above subject, says that, along with the pneumococcus, cold is of great influence in causing pneumonia. Animals which have remained well after an intra-tracheal injection of pneumonic sputum become affected with pneumonia very quickly if exposed, either before or after the injection, to cold. The author thinks that the cold disables the ciliated epithelium of the bronchi, and causes a swelling of the mucous membrane, by which means the entrance of the infectious material into the alveoli is facilitated.

CHRONIC ARSENIC POISONING.

THE theory proposed by Selmi, that toxic gases are formed by the action of microbes on pigments contained in wall-papers and the like, has received additional support by the recent experiments of Gosio in the laboratory of the Public Health Department in Rome.³

¹ Medical Press, December 36.

² Fortschritte der Medizin, December, 1890.

³ British Medical Journal, December 26th.

This observer made nutrient media of potato paste, impregnating them in some cases with arsenious acid, and in others with various arsenical pigments; the nutrient media thus prepared were exposed for some days to a constant current of air, which was drawn over them by means of an aspirator. The air after it had passed over the paste was made to bubble through a solution of silver nitrate, which would detain all volatile arsenical compounds which might have been formed. As a result of this first rough experiment the author found that many moulds and some fission fungi developed on the arsenical media, and that very appreciable quantities of volatile arsenic compounds were given off. Proceeding then to isolate the different species which developed, and testing the action of each on fresh sterile prepared media, he found that only two species — mucor mucedo, and in a less degree penicillium glaucum — were able to split up the solid arsenical compounds as above described. From a great number of experiments he comes to the following conclusions: Mucor mucedo will grow well in presence of a notable quantity of arsenic; it seems to grow more luxuriantly under these than under normal conditions. Many fixed compounds of arsenic, and among them the green pigments ordinarily used, are changed by the growth of these moulds into gaseous bodies, among which is certainly arseniuretted hydrogen. The sulphides are not decomposed like the oxygenated compounds, but their presence in the culture media seems in no way detrimental to the growth of the moulds. Under certain conditions of light, moisture, and temperature, it is possible to obtain arsenical gas by the growth of mucor mucedo (and perhaps other mucorineae) on tapestry colored by either Scheele's or Schweinfurt's green. Thus without denying the possibility of occasional poisoning by detached particles, the author considers he has made out a strong case in favor of the germ theory of arsenical poisoning.

THERAPEUTIC NOTES.

ANTIDOTE IN PHOSPHORUS POISONING. — Bókai and Koranyi¹ recommend a solution of permanganate of potash, of the strength of from one-fifth to one-third per cent. as an antidote in phosphorus poisoning. This solution oxidizes the phosphorus into a harmless phosphoric acid, whereas the solution of permanganate is no stronger than one-half of one per cent. does no harm to the stomach.

EUCALYPTOL.² — Mr. G. Archie Stockwell shows, in the *Bulletin of Pharmacy*, that eucalyptol is not a proper name for oil of eucalyptus, but should be restricted to eucalyptus camphor, this perversion of the word being either due to ignorance or for ulterior ends. Eucalyptus camphor, however, has no therapeutic value beyond that of a good oil, which, as it is a pure terpenes, may agreeably be substituted for common oil of turpentine.

BROMIDE OF ETHYL AS AN ANÆSTHETIC.³ — Witzel reviews the results obtained in four hundred and sixty-five administrations of ethyl bromide as an anæsthetic. The effects were good, except in twenty-eight cases, in which the following disagreeable symptoms were noted:

¹ St. Petersburg med. Works.

² American Journal Medical Sciences.

³ Therapeutic Gazette, January.

Great excitement in nine cases, in four of them with marked sweating; cyanosis in two patients, who were hilarious students; asphyxia, which lasted a short time upon the occurrence of anesthesia in a number of cases, and in two cases long enough to make artificial respiration necessary; indisposition and weakness in the limbs in three of the cases, with severe vomiting; urination in three cases, great sexual excitement more frequently; in two cases 60 and 30 grammes respectively of ethyl bromide failed to produce anesthesia.

PEROXIDE OF HYDROGEN. — Richardson⁴ in a long paper on the medical uses of this substance gives, among others, the following prescriptions:

For a gargar.

R	Acidi tannici	gr. x.
	Glycerin	3 fls.
	Alcohol	3 ss.
	Aqua distil.	3 iv.
	Sol. hydrogen peroxid. (10 vols.) . . . ad	3 viii. M.

For anaemia, and in the first stage of phthisis,

R	Sol. hydrogen peroxid. (10 vols.) . . .	3 liss.
	Acidi phosphori dil.	3 l.
	Syrupi ferri hypophos.	3 iv.
	Glycerin	3 l.
	Aqua	ad 3 vi. M.

Dose, one ounce.

For severe cough,

R	Sol. hydrogen peroxid. (10 vols.) . . .	3 liss.
	Morphine hydrochlor.	gr. ss.
	Syrupi tolu	3 vi.
	Glycerin	3 liss.
	Aqua	ad 3 vi. M.

Dose, one ounce.

Correspondence.

LETTER FROM JAPAN.

YOKOHAMA, JAPAN, January 20, 1892.

MR. EDITOR: — The general hospital here, excellently located on hill, was built about eighteen years ago. It has accommodations for about fifty patients of both sexes. Sleeping arrangements seem to be mixture of foreign and native ways, that is, partly in cots, partly on mats on the floor. Sewers are used to let water run away; but intestinal discharges are received in vessels and carried off. Roses were blooming in the hospital grounds — mid-January.

A Japanese gentleman from the *Kencho* (City Hall), was my friend and guide (in schools, hospitals and language). The physician in charge understood English, without venturing to speak the tongue, which so many of the Mikado's subjects are learning — especially in the last three of the eight years' course in the public schools.

In the vicinity is the "lock-hospital," with room for more than the present inmates. This building was formerly used for a much larger territory. Recently, however, each political subdivision has its own temporary home for the afflicted. A hospital for contagious diseases is situated on the outskirts of the city. January 13th, 120 cases of small-pox were reported in Yokohama, 747 in Tokyo. The local authorities are using vaccination to stay the spread of the disease in both cities; near this city is a crematory, whence the bones alone are taken for burial in the ground; but the old method of inhumation is yet largely practised. Burial of the body is forbidden within the city limits of Tokyo.

In Tokyo, Dr. T. Nakahama (Director of the Tokyo Hygiene Laboratory, Member and Manager of the Central Board of Health), conducted me about the institution under his charge, the chief one of the empire, others being at Osaka and Yokohama. At these laboratories are made

* Asclepiad, Fourth Quarter, 1891.

examinations of all food-stuffs and all other articles connected with the health of the people. As health officer, Dr. Nakahama is obliged to go to various parts of the Empire to investigate epidemics or special diseases, and inspect local sanitary conditions. This place is fitted up with all the modern appliances for chemical analysis, bacteriological studies, etc. During the past few months *tuberculin* has been made, apparently the same as that received from Berlin. Experiments with *tuberculin* are being made on guinea-pigs. Many "cultures" were *in situ*—the various stages of such work in active operation. The museum has an extensive variety of filters, disinfecting apparatus, heating contrivances, models of sanitary appliances, etc. The library consists largely of German publications, with works in other foreign tongues. The periodicals have the familiar look of European and American journals, —German, French, English, American publications.

The government has decided to supply Tokyo with "water-works" extending thirty miles distant to source of supply. The people were largely opposed to this, probably chiefly because of the great expense. But the authority, in this land, is yet in the hands of the intelligent, and the uninformed masses are forced to adopt modern ways that appear to be good, even if "old ways are good enough." The question of drainage, sewerage, etc., must be left, for the present, till the revenue will allow the needed outlay.

A few steps from this institute, is a branch of the University Hospital (to which I referred in a former letter), these two being the only public ones in the city. This is similar in form and accommodations to the other, though smaller. At this season, only about half the space is occupied. In the summer (warm weather) there are many more patients.

The annual reports for the past year have not yet been published.

Very respectfully,
F. B. STEPHENSON, Surgeon, U. S. N.

A NEW AND SAFE WAY OF EXPEDITING DIFFICULT CASES OF LABOR.

BOSTON, February 8, 1892.

MR. EDITOR:—Dr. Marshall L. Brown, in the JOURNAL of February 4th, speaks of a new and safe way of terminating difficult labors by pressure upon the abdomen. I am surprised to learn that it is either new or safe.

My preceptor forty years ago was a well-known accoucheur, and widely demanded as a consulting physician in confinement cases. He practised in my presence, and taught me to add force to uterine action when the uterus was incompetent of itself, and that practice was followed by me for many years.

A case came into my hands from a neighboring doctor who had spent two days and two nights with the young woman in her first confinement. Getting disengaged on the second night and also desiring to be relieved to see other patients, he gave the woman ergot while the cervix was but little dilated. It acted on the muscles of the lower segment as well as on the expulsive muscles, thus holding the child back as much as it was forced downward, causing excruciating suffering, which he relieved by shutting off the muscular action by doses of morphine.

When I reached the case, four miles away, in the early morning, uterine action was almost totally suspended and the cervix dilated to the size of a quarter of a dollar; but all things were natural. Having nothing to do but wait, I returned home, to be sent for when labor started up again, which it did very tardily at eight o'clock that evening. The pains were not strong, and the cervix but slowly gave way before them; I had my forceps with me, but thought that there was really no necessity for their application. Being more familiar with their use to-day, I should probably apply them in a similar case. As it was, I did not, but applied my hand over the uterus pressing and relaxing with the pain. The uterus had been so much exhausted by overaction from the ergot that there was not natural

force to do the work and no prospect for the termination of the labor for a long time. As the cervix became more dilated, I got a strong woman to assist me, the patient making as strong expulsive effort herself as she could. At length she was safely delivered about seventy-two hours from the setting in of the labor.

That this procedure is always safe I do not believe; for I think I had a case in which the child was lost by it. This patient was about thirty-two. She was well developed and vigorous. She had had some half-dozen conceptions, which she somehow lost, the oldest fetus being six months. Everything went well till the cervix dilated to the size necessary to let a six months' fetus pass, when it seemed rigid and unwilling to dilate any further, though the pains were frequent and very strong. I applied such remedies as had reputation in overcoming rigidity. Years before I should have bled such a patient, but did not do it in her case, as the fashions of practice had changed. After many hours of this active work, during which the child was yet alive, the rigidity of the os began slowly to yield, when I began external pressure. Now the pains were long and the pressure correspondingly long, causing strangulation of the cord and the death of the child before it passed the upper strait; this I attributed more to the external pressure than to the uterine contractions themselves, strong though they were. To-day, in a like case, I would give more chloroform, and get on the forceps as soon as I could, deeming it safer to exert traction below than to add the force above when the uterus was itself so strongly acting. Relaxing the cervix by venesection would be the best method, being safer for both mother and child. Since the above I have more rarely resorted to external pressure.

Very truly yours, E. CHENERY, M.D.

RECORD OF MORTALITY FOR THE WEEK ENDING SATURDAY, FEBRUARY 13, 1892.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 13, 1892, TO FEBRUARY 19, 1892.

The leave of absence granted CAPTAIN WALTER W. R. FISHER, assistant surgeon, U. S. A., is extended fifteen days.

The leave of absence on surgeon's certificate of disability granted FIRST-LIEUT. JAMES D. GLENNAX, assistant surgeon, U. S. A., is extended fifteen days.

MUTTER LECTURESHIP OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

The next course of ten lectures under the bequest of the late Prof. Thomas Den Mutter, M.D., LL.D., "On Some Point or Points connected with the Diseases of the Nervous System," will be delivered in the winter of 1892-93, before the College of Physicians of Philadelphia. Compensation, \$900. The appointment is open to the profession at large. Applications, stating subjects of proposed lectures, must be made before October 15, 1892, to

WILLIAM HUNT, M.D., Chairman of Committee,
13th & Locust Sts., Philadelphia, Pa.

APPOINTMENTS.

R. H. FITZ, M.D., has been appointed Professor of the Theory and Practice of Medicine in the Harvard Medical School.

H. P. WALCOTT, M.D., has been elected a Trustee of the Massachusetts General Hospital.

RECENT DEATHS.

LEWIS H. STEINER, M.D. (Penn., 1849), librarian of the Enoch Pratt Library, Baltimore, died February 18th, aged sixty-four. He was at one time editor of the *American Medical Monthly*, and the author of numerous works on different subjects. During the war he was chief inspector of the United States Sanitary Commission in the Army of the Potomac, and after the war reorganized the public schools of Frederick County, Maryland. In 1869 he received the honorary degree of A.M. from Yale College. In 1871 he was elected to the State Senate from Frederick County. When the Enoch Pratt Free Library was established six years ago, Dr. Steiner was elected librarian.

CHARLES PARKE KEMP, M.D., died at Rugby, Tenn., February 12th, aged fifty-one. He graduated from Harvard College in the class of 1862, and from the Medical School in 1866. He served for a year as house-officer at the Boston City Hospital, and then settled in Springfield, where he remained until 1879, when on account of ill health he went to Rugby, where he has since remained.

JAMES SWENNEY, M.D., died in Brooklyn, February 18th, aged fifty-four. During the war he served as surgeon of the 153d New York Regiment. He has twice been a member of the Brooklyn Board of Education.

CELESTE BURNHAM, M.D. (Dart., 1869), M.M.S.S., of Lynn, died February 17th, aged fifty.

A. H. FAQUET, M.D., Professor of Clinical Medicine in the Medical Department of Laval University, Montreal, died recently at St. Cuthbert.

BOOKS AND PAMPHLETS RECEIVED.

A CASE OF DIFFUSE FIBROMA WITH A TENDENCY TO INTRACANILICULAR GROWTH OF BOTH BREASTS; OPERATION ON EACH WITH AN INTERVAL OF THREE WEEKS; RECOVERY.¹

THE SMALLER WEIGHED, AFTER REMOVAL, SEVENTEEN POUNDS, THE LARGER FORTY-THREE; COMBINED WEIGHT, SIXTY POUNDS.

BY C. E. PORTER, M.D.,
Surgeon Massachusetts General Hospital; Professor of Clinical Surgery, Harvard University.

I SHOULD NOT think of asking the attention of such a distinguished gathering of surgeons to the report of a single case, were it not that it falls to the lot of but few surgeons to see such a case, and still fewer to operate upon one.

My patient, Mrs. M., aged thirty-seven, was known

Feeling that loss of blood was one of the dangers, I had made two large skewers; with these I transfixed the breast vertically and horizontally close to the chest wall, and behind them placed a tightly-drawn rubber tourniquet. An anterior and posterior flap was made and the breast removed. All vessels large enough to be recognized were tied with sterilized silk before the tourniquet was removed, and little blood was lost. The operation so far was done in the sitting position; she was then placed upon a table and a few remaining pieces of the breast tissues removed. Continuous silk suture closed the wound, with bone drainage. Six days after the stitches were removed, and there was a slight oozing at two points. Four days later wound solid, and dressed with collodion dressing for support. Three weeks after first operation I removed the remaining breast in the same manner. This was followed by more marked shock than the first, but six hours after she had reacted well and was in good con-

SOCIETY NOTICE.**SUFFOLK DISTRICT MEDICAL SOCIETY, SURGICAL SECTION.**

The Surgical Section of the Suffolk District Medical Society will hold its regular monthly meeting at 19 Boylston Place, on Wednesday evening, March 2, 1892, at eight o'clock.

A report of experimental and clinical investigations into the use of Dermatol will be made by Dr. A. K. Stone.

The general subject for Discussion will be the Surgery of the Liver.

Dr. W. W. Keen, of Philadelphia, will present a paper upon: "Three Cases of Hepatic Surgery: I, Resection of a large portion of the liver for adenoma of the bile ducts, recovery; II, Perforating gun-shot wound of the liver, laparotomy, recovery; III, Cholecystotomy in which the gall-bladder had to be reached through the pancreas, death." Dr. Geo. W. Gay, Dr. A. T. Cabot and Dr. M. H. Richardson will each report Cases of Cholecystotomy; Dr. M. H. Richardson, A Case of Echinococcus Cyst of the Liver; Dr. Homer Gage, of Worcester, A Case of Secondary Laparotomy for Pistol-shot Wound of Liver; Dr. Irish, of Lowell, Cases of Hepatic Abscess; Dr. S. J. Minter, Retention Cyst of Liver.

It seems necessary to remind the members of the Section that the meeting is called for EIGHT O'CLOCK.

CHARLES L. SCUDDER, M.D., Secretary, 94 Charles Street.

... cases could be suspended. Never any pain; appetite good, and sleeps well. Pulse, 96; temperature, 97.8°.

Physical examination shows she is pale, emaciated, with ovarian facies. Both breasts enormously enlarged. Right breast: largest circumference, thirty-eight inches; length from chest wall to nipple, seventeen inches; circumference at base, twenty-three inches. Left breast: largest circumference, twenty-eight inches; length from chest wall to nipple, fourteen inches; circumference at base, twenty-three inches. Skin edematous, thickened and porky. Throughout both are to be felt movable, hardened masses of irregular outline, varying in size from an orange to a closed fist. No tenderness. For two weeks every attention was given to building up her strength for an operation, which in size of wound would equal a hip-joint amputation. At the end of that time she was brought to operation. I decided to remove the left and smaller breast first.

¹ Read before the American Surgical Association, September, 91.

It should now be stated that before she left the hospital my senior house-surgeon called my attention to an enlargement of the uterus, and her history stated that her catamenia had been absent three months before entrance. I told him as she knew nothing about it to let the matter drop. She might be pregnant, and that time would determine; she might have a uterine fibroid, but had better be left to find it out later, for after two such severe operations I was content that she was well. Her condition was not suspected until her convalescence after the second operation.

HISTOLOGICAL EXAMINATION.

The histological report is by Dr. W. F. Whitney, Pathologist to the Hospital.

"The section surface of the growth, which was irregularly divided into lobules, was of a slightly translucent, grayish color, and traversed by numerous irregularly branching chinks or fissures lined with a softer and more grayish opaque substance than the intervening tissue.

diarrhoeal diseases, whooping-cough, erysipelas and fevers) 453, acute lung diseases 725, consumption 340, diphtheria and croup 189, typhoid fever 108, scarlet fever 79, diarrhoeal diseases 34, cerebro-spinal meningitis 28, pneumonia 25, measles 13, erysipelas 11, malarial fever 8, puerperal fever 4.

From diarrhoeal diseases New York 14, Brooklyn 5, Chicago 4, Cleveland 3, Milwaukee and Lowell 2 each, Boston, Cincinnati, Washington and New Bedford 1 each. From cerebro-spinal meningitis Chicago 9, Brooklyn 4, Philadelphia and Washington 3 each, Boston, Milwaukee and Lawrence 1 each. From whooping-cough Chicago 6, New York 4, Brooklyn 3, Philadelphia and Pittsburgh 2 each, Boston, Cleveland, Washington, Portland, Lowell and Gloucester 1 each. From measles New York 9, Brooklyn 2, Chicago and Nashville 1 each. From erysipelas New York and Brooklyn 3 each, Philadelphia 2, Boston, Cleveland and Washington 1 each. From malarial fever Brooklyn 5, New York 2, Chicago 1.

THE SMALLER WEIGHED, AFTER REMOVAL, SEVENTEEN POUNDS, THE LARGER FORTY-THREE; COMBINED WEIGHT, SIXTY POUNDS.

BY C. H. PORTER, M.D.,
Surgeon Massachusetts General Hospital; Professor of Clinical Surgery, Harvard University.

I SHOULD not think of asking the attention of such a distinguished gathering of surgeons to the report of a single case, were it not that it falls to the lot of but few surgeons to see such a case, and still fewer to operate upon one.

My patient, Mrs. M., aged thirty-seven, was born and has lived in Nova Scotia. She entered the Massachusetts General Hospital just at the close of the service of Dr. A. T. Cabot, who did not think her at that time in a condition to undergo such serious operations, and she became a patient of mine in the service following his. Her family history is of no importance. Her personal history is that of ordinary health up to three years ago. Has borne two children, the youngest ten years old. Her catamenia have been regular and normal up to three months ago, when they ceased.

Three years ago she discovered a hard lump in the upper part of right breast, which gradually increased in size, and with it the whole breast. Three months after the right breast commenced to enlarge, the left breast became similarly affected, and at the end of six months the right was the size of a baby's head, and the left a little smaller. For sometime, then, the growth was very gradual; but three months ago a rapid increase took place, and they became so burdensome by their size and weight that she could not work and could stand only for a short time. She is most comfortable sitting with the breasts resting on a pillow in her lap. In the recumbent posture the pressure of the weight and the dragging upon the chest walls embarrass her respiration: so much so, that after her entrance to the hospital a frame was made upon which the breasts could be suspended. Never any pain: appetite good, and sleeps well. Pulse, 96; temperature, 97.8°.

Physical examination shows she is pale, emaciated, with ovarian facies. Both breasts enormously enlarged. Right breast: largest circumference, thirty-eight inches; length from chest wall to nipple, seventeen inches; circumference at base, twenty-three inches. Left breast: largest circumference, twenty-eight inches; length from chest wall to nipple, fourteen inches; circumference at base, twenty-three inches. Skin edematous, thickened and porky. Throughout both are to be felt movable, hardened masses of irregular outline, varying in size from an orange to a closed fist. No tenderness. For two weeks every attention was given to building up her strength for an operation, which in size of wound would equal a hip-joint amputation. At the end of that time she was brought to operation. I decided to remove the left and smaller breast first.

Feeling that loss of blood was one of the dangers, I had made two large skewers; with these I transfixed the breast vertically and horizontally close to the chest wall, and behind them placed a tightly-drawn rubber tourniquet. An anterior and posterior flap was made and the breast removed. All vessels large enough to be recognized were tied with sterilized silk before the tourniquet was removed, and little blood was lost. The operation so far was done in the sitting position; she was then placed upon a table and a few remaining pieces of the breast tissues removed. Continuous silk suture closed the wound, with bone drainage. Six days after the stitches were removed, and there was a slight oozing at two points. Four days later wound solid, and dressed with collodion dressing for support. Three weeks after first operation I removed the remaining breast in the same manner. This was followed by more marked shock than the first, but six hours after she had reacted well and was in good condition. Temperature, 98°; pulse, 80.

In ten days the dressings and sutures were removed, and there were two small stitch-hole abscesses. Convalescence rapid; and in ten days she was strong enough to desire to leave the hospital and visit some friends. There remained two very small granulating spots, and she was advised to report at the hospital soon, in case all did not go well. The sequel of this seems to have been decided by the irony of Fate, for the woman, instead of visiting her friends in the near vicinity of Boston and reporting in two weeks at the hospital, decided in a few days to return home, and took, in the middle of winter, a cold and perilous sea-voyage. She arrived home the day before Christmas, and called her physician to dress two small spots where the cicatrix had given away since she left the hospital. From a letter from her physician, Dr. C. A. Foster, of Bridgewater, N. S., I obtained the following history: At the time he first saw her, temperature and pulse were normal, but she was much exhausted by her sea-voyage and the attendant seasickness, which was violent during her whole passage, and she had suffered much from cold. For about a week she seemed to improve, when she developed erysipelas, first in the region of right breast, and then extending over back and abdomen. This in four days had faded markedly when she suddenly aborted a five to six months' fetus, and died three hours afterwards in collapse.

It should now be stated that before she left the hospital my senior house-surgeon called my attention to an enlargement of the uterus, and her history stated that her catamenia had been absent three months before entrance. I told him as she knew nothing about it to let the matter drop. She might be pregnant, and that time would determine; she might have a uterine fibroid, but had better be left to find it out later, for after two such severe operations I was content that she was well. Her condition was not suspected until her convalescence after the second operation.

"Microscopic examination showed the bulk of the growth to be made up of a fibrous tissue rich in cells, and holding in its interstices considerable thin serous fluid. Imbedded in this were gland acini and ducts widely separated, and into the openings of which the fibrous tissue had forced its way. These could be directly traced into the fissures seen with the eye, the lining of which proved to be flattened epithelial cells. In structure, therefore, the growth is essentially a diffuse intracanicular fibroma, and is not to be regarded in the sense of a true hypertrophy of the breast; which is suggested by the bilateral and external, somewhat symmetrical shape."

Billroth, in the *Deutsche Chirurgie*, on "Diseases of the Breast," says that diffuse hypertrophy develops usually at the time of, or soon after, the first menstruation; most frequently it is noticed from the fourteenth to the sixteenth year. It begins, however, in some cases two or three years after the first menstruation. The development of the hypertrophy then goes on very rapidly for two to four months, and then, as a rule, maintains comparatively the same size, or increases still more with the first pregnancy, then to remain unchanged. In the cases I have been able to collect—nineteen in all—the time of life at which the disease commences varies much more than Billroth states—one being forty-three and another forty-two years old,

and with those who were married, of which there were six, the ages varied from twenty-two to forty-three years. Of the unmarried, of which there were eight, the age varied from fourteen to seventeen years. There were three in which it was not stated whether married or single, and the ages were twenty-two, twenty-six, thirty-five, and there were two in which no age was mentioned, nor whether single or not. In thirteen cases both breasts were affected. Billroth says, in regard to the course of the disease, it alone is established that through the weight of the tumor the ability to do work is most altered, and that, as a rule, the nourishment of the subject of such affliction is bad. Any further constitutional influence does not seem to exist. He considers no constitutional or local treatment except amputation of any avail, and cites three cases, one by Hane, Hess and Glück, where both breasts were removed at separate times with success. Billroth also states that within his knowledge no observations have been made as to whether such hypertrophied glands return to their former shape and size if the person becomes pregnant and nurses her offspring after birth.

In sixteen cases operated upon, nine had both breasts removed, and one, aged only fourteen, had both breasts very large; one was removed and the other diminished in size after her catamenia were established. Six who had only one breast affected had that removed. All

the operations were successful except one in which the patient died on the fourteenth day with fever.

In conclusion, it would seem from this analysis that this disease develops mostly at the age of puberty, that nothing short of removal is of avail, and that only one case in sixteen died.

THE TREATMENT OF GANGRENOUS HERNIA.¹

BY GEORGE W. GAY, M.D.,
Surgeon to the Boston City Hospital.

THE CASES of gangrenous hernia which will receive attention in this paper illustrate four modes of treatment, to wit : The expectant, or do-nothing method, a very good one in its place; returning the bowel, and closing or leaving the wound open; making an artificial anus; and resection of the intestine. Which of these, or other methods, shall be selected in any given instance depends upon many circumstances, such as the kind and condition of the hernia, the age and state of the patient, and various other matters, which need not detain us at present. What to do with a bowel of doubtful vitality is one of those difficult questions which the surgeon is not infrequently called upon to decide at short notice. Individual judgment must determine whether it shall be returned to the abdominal cavity, or left in the ring, or excised; whether the wound shall be left open or closed. Written directions upon this subject are not quite satisfactory. Actual experience is the great teacher. The black, roughened, ash-colored, or ulcerated bowel of undoubted gangrene, is readily recognized. The very dark brown, or mahogany-colored ruptures are the doubtful ones. In cases of doubt it is good practice to reduce the hernia and keep the wound open with gauze, or some form of drainage, thus giving a ready exit to the intestinal contents, should one be required.

Time, and handling of the bowels, are very important elements in these operations, and are to be borne in mind, when deciding whether to make an artificial anus, or to resect the sphecelated structures. Most surgeons will require from forty-five to ninety minutes to excise the intestine, while an artificial anus can be established in a few moments. The ultimate result of the former method is infinitely preferable to the latter, but the immediate risk is greater. If the patient be in *extremis*, it would probably be better to save time by making an artificial anus, and trusting to the future for a closure of the same by nature or art.

The cases suitable for the expectant or let-alone treatment are limited to those, who are in the last stages of collapse. A patient with a cold, clammy, dusky skin; feeble, flickering pulse, or none at all; dull or stupid intellect, will hardly survive any operative treatment. While crossing the ocean some years ago the writer was asked by the ship's surgeon to see a man, who had a strangulated femoral hernia of several days' duration.

To look at the man one would not think that there was much the matter with him. He was quiet, conscious and comfortable. No pain, nor vomiting. All active symptoms had ceased. But he had no pulse at the wrists, and his extremities were cold. In other words, he was in a fatal collapse. Herniotomy was done and a recent, gangrenous knuckle of small intes-

tine was found imbedded in a mass of old, thickened, adherent omentum. Death took place in a few hours.

Several years since I was called out of town to see a man, who had a large, irreducible, scrotal hernia of many years' standing, which had become strangulated three days before. The lower part of the tumor was purple and cold, indicating that mortification had set in. Vomiting and pain had ceased, and the pulse was weak. He was calm, conscious and desired an operation. It was decided to make an effort to relieve the strangulation. The patient took the ether slowly and quietly, but before he was fully under its influence the bronchial tubes filled with mucus or serum from a rapid edema, and death took place at once.

It cannot be questioned that the fatal result in both of these instances was hastened by the operation, and that it would have been better to let them alone, as was done in the following case. An old woman was admitted to the City Hospital last year in a state of collapse from a gangrenous umbilical hernia of two days' duration. Vomiting, pain, delirium, dusky, clammy skin, followed by death in thirteen hours. It did not seem possible for any treatment to do her any good.

It is difficult to indicate upon paper, or even to determine at the bedside, in all cases, the degree of collapse that precludes an operation. My own experience would incline me to take pretty large risks under these circumstances. Much, very much, depends upon the manner in which these patients are managed. Time, animal heat, blood, the anesthetic, moving the patient, and manipulating the parts involved are important factors in the treatment. Briefly, it may be said that the patient should be warmly covered, moved as little as possible, in fact, when practicable, it is better that the operation should be done in bed. Only sufficient anesthetic should be given to deaden, rather than entirely remove sensibility to pain. The operation should be done as quickly as possible. Stimulants are to be given by the skin and rectum unless the stomach can be relied upon, which is seldom the fact during shock, however quiet it may seem to be. Absorption and assimilation are slow and unsatisfactory. Experience justifies the assertion, that, managed in this way, many desperate cases can be carried through an operation in safety. The following instance illustrates the fact.

Mrs. M., aged forty-seven, was admitted to the City Hospital in May, 1891. She was a large, fat woman with an umbilical hernia of five years' duration. Symptoms of strangulation had existed for sixty hours. Skin cold and clammy; pulse rapid and weak. She was restless, respiration was sighing, in short the collapse was very marked. The tumor was black at the apex and as large as the fist. A few whiffs of ether were given, and an incision was made directly into the bowel. The ring was enlarged, and the intestine secured *in situ* by sutures. The patient rallied fairly well, and although she had an attack of acute nephritis, yet she was much relieved by the operation, and lived seventeen days. She died from inanition, apparently due to the high location of the opening in the small intestine. About eight inches of the gut were gangrenous. At no time did the patient's condition justify any attempt at resection of the diseased tissue.

About a year ago I operated upon an old lady, a

¹ Read before the Surgical Section of the Suffolk District Medical Society, January 6, 1892.

patient of Dr. Edson's, who had a gangrenous inguinal hernia. She was extremely weak, vomiting, dusky skin, and feeble pulse. The bowel was laid open by a free incision, the constriction divided, and a poultice applied. She died in a few hours from shock.

Another woman, aged forty-five, was operated upon at the hospital last summer for a very large strangulated umbilical hernia consisting of omentum and intestine. The bowel was in a doubtful condition, but was finally returned. The omentum was cut off, and the ring closed by sutures. The patient only partially rallied, and died apparently from suppression of the urine, in forty hours. No autopsy was made, but there were no signs of extravasation or peritonitis.

Another case of doubtful condition of the intestine terminated more favorably. A woman, aged fifty-five, was admitted to the hospital in April, 1888, with a strangulated inguinal hernia of three days' duration; the rupture was a recent one. On opening the sac the bowel was very dark, but glistened, except in three or four small patches, which were ashy in color and very thin, as though all the coats, but the serous, were perforated. The bowel was finally replaced, as it was thought that the risk to her life would be less thereby, than from a resection of the gut. She was an extremely fat woman, and apparently had feeble powers of resistance. The wound in the sac was left open as well as the external one.

At the end of ten days, feces appeared in the wound and continued to be discharged for about a week. The wound was soundly healed in a month. The provision of a free outlet for the intestinal contents probably saved the patient's life.

The good effects of an operation under the most unpromising circumstances are well shown in a case recently treated at the hospital. A man, aged sixty-eight, was seen at the end of five days' suffering from a gangrenous inguinal hernia. Vomiting, hiccup, pain, delirium, dusky skin, weak, intermittent pulse were the symptoms. The rupture had only existed a week. The patient was not removed from the bed, but was surrounded with heaters, stimulated by skin and rectum. A very little ether was given, and an opening rapidly made into the intestine. No efforts were made to separate the gut from the sac, but a herniotome was passed into the bowel, the constriction was cut and the wound lightly packed with gauze. The operation occupied but a short time, and the patient suffered no additional shock thereby. The hiccup persisted for a week. In five weeks two-thirds of the feces came through the rectum. He was discharged from the hospital in very good general condition at the end of forty-one days. A little thin watery fluid came from the wound for some time after he went home. He returned to his business as a printer, although not able to do much work. The sinus has not yet healed, it being over four months since the operation was done, but he is able to be out and about. As a rule, the sinus does not give him very much trouble.

Two cases of resection of the bowel have come under my care; one recovered and one died. A woman, aged six, entered the hospital last June suffering from a large umbilical hernia, which had existed fifteen years. It was gangrenous and had been strangulated twenty hours. Sac contained a large mass of more or less adherent omentum, in the midst of which, was a knuckle of black intestine. The former was tied in

sections and cut off. Five and a half inches of the bowel were cut away with its accompanying omentum, the ring having first been freely divided to allow the bowel to be brought out into easy reach. The vessels having been tied, the mesentery was adjusted with a continuous silk suture. The bowel was closed by two rows of continuous silk sutures, one including the muscular coat, the other, a Lambert, involving only the serous layer. External wound closed.

Patient had some pain after operation. Bowels moved the next day, and also on the following day. Temperature rose gradually till the third day, when it was 103°. Some distension; delirium, pain, restlessness and prostration. Wound quiet; no abdominal tenderness. Sank and died on the fifth day.

An autopsy showed fecal extravasation at the junction of the intestine and mesentery, as is to be seen in the specimen here presented. It will be noticed that union seems to be firm and complete everywhere, except for about half an inch, as indicated above. Perhaps this patient would have done better had the wound been left open and packed with aseptic gauze.

The next case operated upon precisely the same manner, so far as the intestines was concerned, made a good recovery.

Mrs. K., aged fifty-five, entered the City Hospital October 16, 1891. She rode upon the front seat of the ambulance with the driver, although she had a large, gangrenous umbilical hernia of about two days' duration. She was pale, haggard, weak, pulse irregular and feeble. Vomited after admission. An enema of brandy and strong black coffee having been given, also a hypodermic injection of morphin, she was partially etherized, and the sac laid open. The inside of the sac was dark colored and contained about six inches of small intestine, which was black and mottled with grayish spots, indicating sphacelus. All of the intestine seen was covered with a layer of lymph. The destructive process extended about half way to the root of the mesentery.

The gangrenous tissues were removed with knife, and the bowel and mesentery united as described in the last case. Wound closed after approximating the ring with two strong silk sutures.

Notwithstanding the fact that this woman had a fibrous tumor as large as a child's head, and a considerable amount of ascitic fluid in the peritoneal cavity, she made a speedy recovery from the operation. The wound healed by first intention. The bowels moved spontaneously on the third day, and regularly afterwards. She had little or no pain, required very little medicine of any kind, soon regained and kept a good appetite. She left the hospital in five weeks in a most satisfactory condition. The wound was firmly healed, there was no protrusion at the navel, and the functions of the bowels were in a natural state. In other words, so far as concerned the hernia, she was well.

Patients in profound collapse from gangrenous hernia had better be let alone. If the prostration be too severe to allow a prolonged operation, an artificial anus may be established for a time, the closure of the orifice being left to future efforts of nature or art. If the condition of the strangulated parts be doubtful, they may be replaced, and the wound packed with sterilized gauze. Under all circumstances the constriction must be relieved, and a free outlet provided for all obnoxious matters.

THE MANAGEMENT OF GANGRENOUS HERNIA.¹

BY HERBERT L. BURRELL, M.D.,
Assistant Visiting Surgeon, Boston City Hospital.

WHEN an operator has exposed a loop of intestine which is lustreless, mottled with chocolate-colored blotches from having been caught in one of the abdominal rings, an imperative question arises of what shall be done with this threatened gangrenous hernia. When the intestine is perforated, the operator's course is much clearer than where a threatened perforation exists; for the presence of the perforation indicates that either the intestine must be resected, or attached to the ring, and an artificial anus established.

There are three methods to be considered: First, a return of the bowel to the abdominal cavity after freely dividing the ring, and packing the canal down into the peritoneal cavity with iodoform gauze; second, an immediate resection of the intestine; third, allowing the intestine to remain *in situ*, after division of the constricting ring, that its condition may be known as the case goes on. Placing doubtful intestines inside the peritoneal cavity has always seemed to me a source of danger.

Intestinal resection is a procedure attended by great risk in the length of time consumed and the shock added to the patient's condition, so that it has seemed to me that in the majority of cases it would be better to leave the intestine *in situ*, that its fate may be watched, that it may be outside of the peritoneal cavity, and thus danger of infection be minimized. I have had four cases of gangrene of the intestine, the details of which I will present:

CASE I. J. H., a healthy young man, entered the Boston City Hospital. For five years he has had an inguinal hernia on left side, which has bothered him a little, but it has usually been easily reduced. Yesterday, at 4 p.m., the hernia came down, and could not be put back. A good deal of force was used by a friend, who felt sure that he could reduce the hernia by taxis. In the left inguinal region there was a prominent tumor, extending into the scrotum. The testis formed the end of the tumor, apparently forced down under considerable tension. An incision was made, two and one-half inches long, over the hernial sac into the left lower abdomen, and nearly at right angles with the median line of the body. It was found impossible to reduce the hernia at this point, and a second incision was made at right angles to the first, over the hernia and down to the scrotum. The dissection was carried down until the sac was reached and opened. A piece of omentum, the size of the fist, protruded from the sac. Around this was a coil of intestine, seven or eight inches long, of a dark plum color. The ring was enlarged, and after considerable difficulty the omentum and intestine were replaced. The difficulty of replacing was due to the omentum being caught by the loop of intestine. The primary wound was diminished in size by sutures, and the wound was packed with iodoform gauze, leaving a direct channel to the peritoneal cavity. Operation lasted fifty-six minutes. The patient was in fair condition, having been vigorously stimulated.

Second day. Patient rather better to-day, and has no vomiting. Says he feels like having a movement of the bowels.

¹ Read before the Surgical Section of the Suffolk District Medical Society, January 6, 1892.

Third day. Patient much more comfortable, temperature nearly normal, and no pain. Sleeps well, and begins to have a good appetite.

Fourth day. Patient does not feel like having a defecation yet. Tongue has a whitish coat.

Fifth day. This morning the dressing was found soaked with fecal matter. The bowel has undoubtedly sloughed. (Later a distinct segment of the ilium came away, two and one-half inches in length, and including the lumen of the intestine.) The wound thoroughly irrigated and cleansed. Patient's condition much the same. Wound to be dressed every six hours, and thoroughly cleansed.

Sixth day. Patient very comfortable.

Seventh, eighth, ninth and tenth days. Patient in very much the same condition.

Twelfth day. Complains of a transitory bunch coming around the artificial anus, which gives him a good deal of pain. Wound has granulated remarkably quickly, so that it is nearly closed, and the drainage is not good. Could not introduce a drainage-tube, so stool sounds will be passed from day to day.

Thirteenth day. No discharge from abdominal wound.

Fourteenth day. Patient feels like having a defecation.

Fifteenth day. Patient had a chill at 2 p.m. Temperature returned to normal after a few hours, and the patient felt much better.

Sixteenth day. The patient received an enema, which brought away considerable feces. Since then he has had several dejections of formed feces, normal in appearance. Almost no discharge from the external wound, which is nearly closed in.

Eighteenth day. Chill at 5 p.m. All sutures taken out to day. Movement of bowels nearly every day.

Nineteenth day. The external wound has broken down again, and there is a great discharge of fecal matter. None by anus.

Twenty-first day. External wound still discharging. Has had very little feces by anus.

Twenty-first day. Has had a good deal of pain. Fistula still open and discharging.

Twenty-third day. All feces now by fistula, some wind passed by rectum.

Twenty-fifth to thirty-fifth day. Patient in very much the same condition, occasionally passing feces by abdominal wound, but usually per rectum.

Thirty-fifth to forty-fifth day. Patient's condition is much the same. He thinks he has gained a little strength lately, but there is no marked gain. Abdominal wound much the same.

Forty-fifth to fifty-sixth day. Patient in very much the same condition. Occasionally has sharp attacks of pain referred to the abdominal wound, and a coil of intestine can be mapped out at this point when the pain is severe. The patient's friends removed him from the hospital and from the city, and since that time I have been unable to keep track of the case.

CASE II. P. S., age seventy-two. The patient does not understand English very well, and cannot give an accurate account of himself. According to his own statement he has had a reducible femoral hernia on the right side five years. Three days ago began to have pain across the upper half of the abdomen and in the region of the rectum. He has not been able to reduce the hernia for three days, and has had no defecation. Has vomited repeatedly, and feels very sick.

An old, broken-down, poorly-nourished man. There is a tumor in the right groin about the size of a hen's egg. It is below Poupart's ligament, and is not reducible. The patient is pale, pulse weak, temperature about 98° , face haggard, tongue coated, seems on the verge of collapse. Moderate abdominal tenderness and distension.

The patient was put under primary anesthesia, and a nearly vertical incision, about three inches long, was made, and the hernial sac exposed. On opening it, a few drachms of sero-sanguinous fluid escaped. The intestine was found to be chocolate-colored, mottled in places and collapsed. The sac also contained a piece of omentum the size of a walnut. The ring was divided freely on the forefinger, the omentum reduced, the intestine was sewed to the abdominal ring, and an incision was made into the projecting loop of intestine. A small amount of feces escaped. A dressing was quickly applied, the patient was put to bed and actively stimulated with heaters. The operation lasted thirteen minutes.

First day. The dressing, when removed, was filled with feces, patient's condition is bad, pulse poor, extremely restless, temperature 99° . In the evening required restraint. Took nourishment fairly well. Discharge from the artificial anus free.

Second day. Patient failing rapidly. Did not rally under the influence of stimulants, and died.

CASE III. H. D. R., age sixty-eight. Patient has had a hernia for three years, which has given her little trouble. There has been extreme constipation. She was poorly developed and nourished. There is a tumor over the left inguinal canal about as large as a good sized plum, semi-fluctuating and very tender to the touch. Her abdomen is distended and very tender in the dependent portions on palpation. Pulse is very fair in strength and rhythm. Facies anxious, extremities cold, vomiting. Hernia has been down three days.

An incision was made over the tumor two inches long, the layers were dissected away, and the sac opened. A bloody fluid escaped, disclosing the intestine. The latter was glossy and here and there badly mottled. The finger passed up to the ring disclosed a tight stricture. This was divided with scissors. Adhesions were found to exist around the bowel as it lay in the inguinal canal. Stitches were taken between the bowel and the sac, and the bowel was opened. A certain amount of feces escaped, semi-fluid in character.

Second day. Wound looks well, less pain over abdomen, takes treatment well, no vomiting. Urine, albumen 1-8 per cent., acid, 1027, sediment, hyaline, granular, fatty casts, renal granular cells, fatty and granular renal cells, vaginal and bladder cells, blood and pus.

Third day. Much more comfortable, very thirsty, takes champagne and coffee *ad libitum*.

Fourth day. Much better, complains of some pain about the lower abdomen on having a passage from the artificial anus. Eats well. No especial discomfort. Dressing changed every six hours.

Fifth day. Shows a tendency to collapse. Pulse rapid and jerky. Still has pain on having a movement of the bowels.

Sixth day. Rather better. Complains of less pain, takes stimulants unwillingly. Bowels move regularly through the artificial anus. A large piece of bowel

has sloughed about two inches square. No hemorrhage.

Seventh day. Rather more pain. Controlled by morphine, pulse seems weaker. Extremities are not especially cold. Skin clammy.

Eighth day. Patient passed the night in a comatose state, pulse gradually grew weaker and extremities colder. Died soon after midnight.

At the autopsy, it was found that although the artificial anus had relieved the strangulation of the intestine, there was a twist in the ilium which rendered the greater part of that portion of the intestine gangrenous (a distance of about eight inches). It was perforated at two points, and feces had escaped into the peritoneal cavity.

CASE IV. J. S., a strong, healthy adult, age twenty-eight. Has had a right inguinal hernia for three years. Has never worn a truss. Five days ago, while lifting a bale of cotton, felt the hernia come down, was unable to reduce it, and has applied for assistance to two physicians who declined to treat him, and advised him to enter a hospital. Has been in intense pain. The abdomen is distended, is vomiting a coffee-ground-like material. Temperature 100° , pulse 130, small. Tongue dry and brown, very thirsty, extremely anxious. The danger of his position having been explained to him, he was put under light anesthesia, and an incision was made down to the intestine. A gangrenous loop of intestine, probably a portion of the ilium, was found glued in the hernial sac. The ring was divided freely, and the intestine remained *in situ*. An incision was made into the intestine, and a large amount of fluid feces escaped.

Operation twenty-five minutes. Patient put to bed with heaters, subcutaneous injections. Seen at the end of three hours, at which time he was comfortable with a temperature of 99° , pulse 140.

Second day. Patient has discharged an enormous quantity of feces from the opening. The abdomen is less tympanic, temperature 101° , has considerable pain in the abdomen, has vomited three times, but retains some champagne. Discharge of feces from artificial anus good, wound is looking well.

Fourth day. Retains nourishment, has had a small defecation from rectum.

Fifth day. Temperature normal, vomiting has ceased. A large defecation from rectum. Wound looking very well. A piece of intestine about an inch square separated.

Sixth to ninth day. Patient doing well, wound closing rapidly.

Fifteenth day. The wound was closed to about the size of a lead pencil. There was obstruction to the discharge of feces and it was found necessary to introduce a drainage-tube, which gave the patient a great deal of relief.

Forty-second day. The wound had closed completely, the patient was having normal movements. The patient was seen two years later at which time he had suffered no inconvenience from the operation, and considered himself cured. Wore a truss constantly, and has a distinct impulse under the scar tissue.

I have never attempted to do an intestinal resection for gangrenous hernia, and have always felt that it was a hazardous undertaking, and that it would be better to establish an artificial anus, and if the patient recovered to do a secondary operation and resect the intestine at one's leisure. The first case is extremely

interesting, for there was but little in the patient's condition after operation to indicate the sloughing of the intestine after it had been replaced in the peritoneal cavity. The sloughing of the intestine, and the discharge of feces, occurred the fifth or sixth day, and by this time the intestine must have been walled off from the peritoneal cavity. This wall of inflammatory material, as thrown out, must have been a protection to the general peritoneal cavity, but the packing of the wound as carried out in this case has seemed to me a matter of a great deal of importance, in that it allowed a free exit for the feces. The chills which he had were apparently associated with a diminished discharge from the artificial anus. For weeks I stood ready at any time to do an intestinal resection, upon the slightest failure in the patient's general condition, but at no time did the symptoms seem severe enough to indicate that course. When he left my care he was apparently on the road to recovery, and the outcome of the case will be one of great interest.

In the second case the patient was an old, broken-down, poorly-nourished man, with a gangrenous femoral hernia, and on the verge of collapse. The operation was a desperate measure, and can only be said to have relieved the acute suffering.

The third case seems to me to demonstrate the advisability of thoroughly exploring the canal, and drawing out a loop of the intestine to determine how far the gangrenous process has extended. Unless this is done and the intestine is allowed to remain *in situ*, one, at times, will be deceived by gangrenous intestine remaining in the peritoneal cavity.

The fourth case was successful, from the fact that he was a vigorous adult. The closure of the intestine after a separation of a slough of an inch square has seemed to me a matter of importance, particularly when it is considered that two years later the patient was seen and expressed himself as free from all symptoms which would indicate the formation of a stricture of the intestine.

I will attempt to formulate, for the purposes of discussion, the ideas I have formed from a consideration of these cases.

Questionable gangrenous herniae should be treated either extra-peritoneally or by immediate intestinal resection. Whether to treat a gangrenous hernia extra-peritoneally or by resection must depend entirely upon the individual case, and the following factors should be considered:

(a) The general condition of the patient.

(b) The age of the patient.

(c) The length of time the hernia has been constricted. [This in relation to the probable time at which the intestine will give way, and the extravasation of feces takes place.]

(d) The circumstances under which the operation is performed, whether the surgeon is ably assisted.

(e) The portion and amount of intestine involved; for in some instances where an artificial anus is established high up in the intestinal track the patient is practically starved to death.

The management of a gangrenous hernia requires prompt and accurate judgment, founded on a large experience, and it is only by carefully formulating our ideas that we can meet the emergency with intelligence.

THE port of Santos in Brazil is still infected with yellow fever.

Clinical Department.

A CASE OF INTESTINAL RESECTION AND SUTURE FOR ARTIFICIAL ANUS FOLLOWING GANGRENOUS HERNIA.¹

BY MAURICE H. RICHARDSON, M.D.

RAYMOND S., aged twenty-two, entered the Massachusetts General Hospital on Tuesday, October 1, 1891. About ten years ago he noticed a lump at the upper end of the scrotum on the right side, which would disappear only on lying down. Sometimes, after remaining down for quite a little while, the lump would get hard and painful. Nothing was ever done for it. On the 19th of June, 1891, he was taken with a sudden pain in the stomach. The tumor grew much larger, and he began to vomit almost immediately. The pain soon became so severe that the attending physician, Dr. Woodworth, of Canard, Nova Scotia, was sent for.

Dr. Woodworth first saw him at about eight o'clock on June 19th, and found him suffering from an obstructed hernia of a few hours' standing, which had come on while striking at a ball. There was a tense tumor in the right scrotum, and suffering was severe. Chloroform was given and taxis carefully tried, without success. A consultation was called, and fresh attempts made at reduction. There was no vomiting, and there were no constitutional symptoms. After local application of cold, taxis was again tried under chloroform, without avail. On account of the absence of constitutional symptoms and other evidence of obstruction, operation was postponed. Meanwhile, cold applications were continued.

Swelling increased in the region of the tumor until the penis was so involved that it was necessary to use a catheter. The temperature was never above normal except once, when it stood at 99.5°. Cold was applied for sixty hours without reduction. The lower bowels had been opened freely, and strength was well sustained. In about a week a soft point was noticed over the hernia in the lower part of the scrotum, and soon fistulae formed at this point with the escape of feces, and, in the course of the following week, there escaped some ten or fourteen inches of intestine. During this time the pulse never exceeded 90 and the temperature was normal. He often had quite free movements and declared that blueberries, which he ate while in bed, passed by the rectum. From this evidence, it seemed to the attending physicians that the alimentary canal was not entirely cut off, and it seemed unaccountable to them that the constitution should be so little affected by all the local suffering and disease. On his recovery of the immediate effects of the strangulation, he was sent to the Halifax Hospital, where, on every second day, or thereabouts, he would have a passage of feces through the natural channel — sometimes from a warm water injection, but more often without anything. After being in the hospital for some time, he was removed to another, smaller hospital, where one of the abdominal openings was enlarged.

At the time of his admission to the Massachusetts General Hospital, he was passing gas and some fecal matter by the rectum. As long as the fistula remained open he suffered no pain. On examination, the right inguinal region was found riddled with openings through

¹ Read before the Surgical Section of the Massachusetts Medical Society, January 6, 1892.

which fecal matter almost constantly escaped. The right testicle was drawn up nearly into the external ring. The skin was infiltrated, edematous and red, and there was considerable inflammation in the adjoining parts. His discomfort was so great as to be quite unbearable and life hardly worth living. He spent all his time in bed, wiping up with cloths the discharges which were constantly escaping through the numerous fistulae.

After a careful study of the case, in spite of which it was impossible to make out definitely the condition of the bowel ends or the direction of the sinuses, it was decided best to attempt the restoration of the alimentary canal. The history and physical examination made it quite apparent that the bowel had sloughed to a greater or less extent, but it was impossible to say that there was not still existing some communication to account for the occasional passage of feces by the rectum. The foul condition of the parts was so marked that it seemed unduly hazardous to open the abdominal cavity through the sinuses. There was no improvement in this respect, however, after constant and prolonged daily efforts at cleanliness, both on the part of the nurse and of the patient. The operation was planned with especial reference to the necessarily foul condition of the parts and the great danger of infecting the peritoneum. My hope and intention was to lay open the numerous sinuses by one long incision, curette them, and by some means to establish a communication between the upper and lower segments of the bowel from their interior. On exposing the external ring, I found two constricted openings side by side, into both of which it was quite feasible to introduce the index finger. Both segments were adherent to each other and to the surrounding parts. In separating the adhesions between the bowel and the abdominal wall for the purpose of making an anastomosis between the adherent segments, the peritoneal cavity was opened. During these manipulations several ounces of fetid pus welled from below the ring and apparently polluted every part of the wound, including the prolapsed healthy intestine. The chief objection in this case to resection and suture had been the danger of infecting the abdominal cavity by the foul discharges of the sinuses and the septic condition of the parts. The force of this objection was lost in separating the adhesions, and I determined at once to make a complete resection of the exposed ends. About two inches of bowel were cut off from each end with the scissors, together with a wedge-shaped piece of mesentery. The bowel ends were held by assistants while interrupted Lambert sutures were applied in a single row, both to bowel and mesentery. The joint seemed very perfect and satisfactory. The bowel was then returned to the abdominal cavity and kept directly under the abdominal wound by means of iodoform gauze, which was placed just in contact with the line of suture throughout its whole extent. It will be seen that the approximated bowel ends and sutured mesentery were everywhere protected with gauze, and that the line of suture was everywhere provided with gauze drainage in case one or more sutures should give way. The external wound was also packed with iodoform gauze and aseptic dressing of cotton tightly swathed outside the whole. During the operation there was frequent and thorough irrigation with warm water. The time of the operation was one hour; of applying the suture twenty minutes.

On the following day the patient was in a remarkably good condition, bright and cheerful. On the second day he passed gas through the rectum for the first time since June. On the sixth day he was put on extra diet. He had a large movement of the bowels, and said he felt "first-rate." The wound was clean and granulating. The gauze was taken out, little by little, until November 12th, when it had been almost entirely removed. The wound was granulating, with still some slight redness and induration about the margin. On November 15th the last piece of gauze was removed and the wound much closed up. On December 11th, the wound was perfectly solid, and the patient felt perfectly well in every way. The bowels were moved nearly every day. He was transferred to Waverley, and has remained well ever since.

This case seems to me to be of value from the fact that the foul condition of the wound did not infect the peritoneum, and that it was possible to go through the manipulations of an extensive operation without ill results attending. The foul condition of the parts in this case led me to select a method by which, if possible, the peritoneal cavity could not become infected. The only way in which this could be done was to make an anastomosis between the proximal and distal ends of the intestine by working from the interior. The success of this procedure would depend obviously upon adhesions between their peritoneal surfaces. For, in the absence of such adhesions, it would be impossible to establish a safe communication by any imaginable method of intestinal suture. Careful attempts in this direction were followed by separation of adhesions and exposure of the peritoneal cavity. It would have been impracticable to establish satisfactory communication in this way, and I believe valuable time was lost in attempting it as a preliminary measure. Even if successful, it does not follow that the sinuses will become closed, nor that the anastomoses will remain permanent or efficient.

When the peritoneum has become thus exposed to the danger of infection, we must choose between anastomosis and end-to-end suture. The latter method I believe to be better, because it seems to me quite as quickly applied, and as secure, while there is practically no danger of stricture. The great danger in both methods is from giving way of the stitches and fecal extravasation. By applying gauze to the line of suture this danger is reduced to a minimum, for such good drainage is provided that nothing more than a temporary fistulous track is likely to remain.

THREE CASES OF THE SEPARATION OF THE EPIPHYSIS AT THE HEAD OF THE FEMUR.¹

BY E. H. BRADFORD, M.D.,
Visiting Surgeon, Boston City Hospital.

THE following cases are reported on account of their rarity:

CASE I. A boy, seventeen years old, fell from a window striking upon a shed of the story below. He was brought to the hospital with symptoms suggesting a fracture of the right limb. On examination, however, no fracture was found at the leg or of the thigh proper. The limb was held in a position of eversion and was slightly shortened, but no injury was discovered below the trochanter, which rotated on twist-

¹ Read at the Surgical Section of the Suffolk District Medical Society, January 6, 1892.

ing the leg. On examination under an anesthetic, abnormal mobility and a cartilaginous crepitus was determined between the head of the femur and the trochanter. The trochanter was higher on the affected than on the other side. The diagnosis of separation of the epiphysis was clear as the symptoms pointed to a lesion in that part and union of the epiphysis does not take place until the eighteenth year.

CASE II. A healthy boy, sixteen years of age, reported himself for examination with the following history: He had been perfectly well, and had not been lame. On attempting to milk a cow, seated on an ordinary milking-stool, he was kicked at by the cow and turned quickly to avoid a blow, suffering a sensation of sudden pain. Immediately after this he was unable to step and was taken to the house, being obliged to remain in bed several weeks.

He was etherized and the limb, which was flexed, painful and useless, was put into position, and made a recovery, but he was able to walk about only with crutches for some time. At the time of examination, three months later, he walked with crutches and could walk without, but with marked lameness. He suffered no pain. An examination showed that the affected limb was shorter by an inch than the fellow. The trochanter was above the Nelaton line to that extent. The motions at the hip-joint were perfectly free, with the exception of inversion, which was not possible beyond the right angle. It was entirely free on the other side. The patient was perfectly well and had not been lame before this accident.

CASE III. A child, seven years old, of fairly good health, but of imperfect assimilation, sustained a fall from the window in the first story. The patient was taken up, placed in bed, and complained of great pain; but no injury of the limb was determined at the time. The child was of a nervous type and it was thought that her symptoms were due to fright rather than to any injury to the bone. She remained in bed for several weeks, finally was able to get up, and after a while to walk, though she still limped. Upon examination, four months after the accident, it was found that the head of the trochanter was half an inch higher on the right, the affected side, than normal. The head of the trochanter was also placed more posteriorly than is normal, and the foot everted. The motions at the hip-joint were free, with the exception of the inversion which was not possible beyond the vertical. The patient was free from pain and able to walk. A rotation of the thorax had taken place in the four months and the ribs on the right side projected.

Cases of this lesion would appear to be quite rare and the diagnosis is not so easy as might at first be imagined at the time of the accident, unless an anesthetic is used. The shortening, though present, is not always recognizable except on careful measurement, and that is not easy in a patient in a sensitive condition. No fracture can be determined by ordinary palpation, and it would appear that slight motion of the limb is sometimes possible, though accompanied by pain. An anesthetic is needed to establish a diagnosis with accuracy in a fresh case.

The symptoms of pain in the separation of the epiphysis are often not greater than what is seen in cases of synovitis of the hip-joint following severe injury or sprain, and unless the patient is anesthetized, the actual condition of things might not be recognized.

In the last edition of "Hamilton's Surgery" (revised

by Smith) one case of supposed separation of the epiphysis is mentioned by Smith, who also quotes in the literature, five cases of separation of the epiphysis, one in a boy of ten, another in a girl of sixteen, another in a boy of fourteen, and two in children of fifteen, the sex not being given. It may, therefore, be assumed that the accident is not a common one. Smith also collected eighty-four cases of fracture of the neck, with the youngest at an age of twenty-nine years. Hyde² collected sixty-one cases fracture of the neck, the youngest being nineteen years of age. As the epiphyseal union is said to take place at the head of the femur at the age of eighteen, this case of Hyde's should probably be classed as a fracture.

The treatment of this condition where it is recognized is, of course, simple. It consists in the ordinary treatment of a fracture, and prognosis is, of course, unusually favorable. Where the condition is not recognized, and a union has taken place, with the resulting deformity, operative interference — osteotomy of the neck of the femur — has been performed by Professor Hoffa, of Wurtzburg, with success.

It would seem that the operation is not a dangerous one, and recommends itself in all cases of marked deformity as a means of curing the disfiguring limp.

In addition to the previous cases the following deserves mention in this connection as a fracture of the neck in a comparatively young person, the patient being younger than the youngest case of Smith, though older than the youngest of Hyde's cases.

The patient was a woman, twenty-two years of age, a Swede by birth,³ and of excellent health and strength. She fell twenty feet. Was unconscious two or three hours, and was brought into the hospital two days later. Examination was made under ether by Drs. Gavin and Burrell and the following symptoms were noted: The left leg was found from half to three-quarters of an inch shortened. There was slight inversion, inability to raise the heel, no deformity, abnormal mobility and marked crepitus at the position of the neck of the femur. The patient was treated by a Buck extension, and made a perfect recovery with no appreciable shortening.

Reports of Societies.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

CHARLES L. SCUDDEER, M.D., SECRETARY.

REGULAR meeting, Wednesday evening, January 6, 1892, DR. A. T. CABOT in the chair.

DR. GEORGE W. GAY read a paper on

GANGRENOUS HERNIA.¹

DR. M. H. RICHARDSON reported a second successful case of

INTESTINAL RESECTION AND SUTURE FOR ARTIFICIAL ANUS FOLLOWING GANGRENOUS HERNIA.²

DR. E. H. BRADFORD: My experience consists of three cases of gangrenous hernia, all fatal. I will not

¹ See page 207 of the Journal.

² See page 211 of the Journal.

¹ New York Medical Record, 1875.

² City Hospital Records, vol. 202, p. 82.

give the details any further than that the first was treated by the formation of an artificial anus, and the patient recovered from the operation, and died of starvation, owing to the short distance of the anus from the pylorus. The second was an elderly lady over seventy. The hernia was found to be gangrenous, and no intestinal suture was made, but the gut was brought to the wound and stitched. The patient died a day after the operation. Third was a case in which resection of the intestine was done, and the patient recovered from the operation. The ordinary steps of the operation as mentioned were performed. Three days later the patient died. At the autopsy it was found the intestine had united perfectly with no leakage, but the patient had died from vomiting. It was found that the lumen of the intestine was too small. This was an accident in the technique which had not been foreseen.

In regard to the treatment of gangrenous hernia, I suppose we are all agreed that in case the patient has strength to warrant it during the operation for gangrenous hernia, resection should be done. In patients who are exhausted, an artificial anus would be preferable.

DR. H. L. BURRELL read a paper on the

MANAGEMENT OF GANGRENOUS HERNIA.⁸

DR. A. T. CABOT: The cases that have occurred to me have really been ones that have had very little interest in connection with this discussion. Two of them were almost moribund at the time of the operation. They were both of them internal strangulations with large extents of intestine gangrenous, all the way from three feet in one case to twenty to twenty-five inches in the other. In those, of course, the only thing to do was to bring the gangrenous intestine outside of the abdominal cavity, and hope for an artificial anus. In neither case was that successful, because the patients had not the strength to rally from the condition.

The third case was interesting as being one in which the gangrene had just succeeded in opening the bowel when the sac was opened. It was a small femoral hernia, a little knuckle of intestine. The sac was a double sac often seen in the femoral hernia. There was a little opening about as large as the point of a lead pencil allowing a little spurt of fecal matter to appear. The patient's condition was so bad that it seemed unwise to attempt a suture of the intestine. It seemed as if in that case it would be unsafe to simply relieve the constriction and leave the intestine *in situ*, because it was so likely to escape from its attachment to the ring and fall back into the peritoneal cavity and discharge its contents; consequently a stitch was passed somewhat as in doing Littré's operation for artificial anus in the groin. On incising the constriction there was a very large escape of fecal matter. The constriction was entirely relieved, but the patient had not the strength to rally, and lived only a few hours after the operation.

I speak of that case mainly as being an illustration of one kind of case in which it did not seem to me safe to simply leave the intestine *in situ* and relieve the constriction, but where it seemed necessary to attach the intestine in its position so that it should not escape and discharge its feces internally.

My feeling in regard to the kind of operation which should be done is, I think, exactly in accord with what

has been expressed this evening by almost every gentleman, that is, that if the patient's strength permits of it, circular enterorrhaphy and return of the intestine to the abdominal cavity would be the course to pursue. It seems to me that that proceeding carried out in Dr. Richardson's case is an excellent one in these cases to prevent the possibility of trouble from the stitches giving way, that is, to provide for drainage by packing gauze down to the wound in the bowel. If the stitches do not yield, the opening very quickly closes, whereas, if they do yield, it is of the greatest importance to allow the escape of feces.

I think I have never done the operation of enterorrhaphy for a gangrenous hernia. It seems to me that the circular operation which was done and described by Dr. Richardson is the best in these cases, although a good many operators are in favor of sewing the two ends of intestine up, closing them quickly and then performing lateral anastomosis with Senn's plates, Abbe's rings or some contrivance of that sort. It seems to me that the result of all of the intestinal sutures I have seen at autopsy have been such as to encourage me to try to establish a union more as nature does it, that is end to end rather than side to side, as this method with Senn's plates; and, as I have seen it done, it certainly has seemed to take very little if any more time. Dr. Halsted claims that he is now able to do circular enterorrhaphy in what is practically only a few minutes. With a little practice I think that operation can be done nearly as quickly as the other, and is preferable in establishing a state more nearly approaching the physiological one.

DR. C. B. PORTER: I came to listen rather than to speak to-night, because I have had no opportunity to prepare anything in detail. My house-officer has sent me a copy of the notes of two cases which have been years ago reported here. I should like to speak of them, not going into the detail of the whole clinical history of the case.

I think that I did the first intestinal suture done in Boston, in 1883, in a woman about sixty years of age. Previous to that she had been operated on for strangulated right inguinal hernia, eight inches of intestine removed, and an artificial anus formed. She entered the hospital, and was under care of Dr. Homans, who operated on September 12th of that year by refreshing the edges of the artificial anus and endeavoring to close it in that way. That closure was successful for a few days, but broke open in about a week, and the patient's condition was the same as before. I operated by uniting a number of fistulous tracts which discharged feces and pus, and, exposing them all down to the ring, opening up the ring, releasing the intestine from its attachments and bringing out the intestine entirely free from any attachments except those of the mesentery into the wound, and found that there was an artificial anus or two opening into the gut, one in the large and the other in the small intestine, and close to each other at the ileo-caecal connection. I united those, and found the larger part of the wound was in the large intestine, and it was a question of how to adjust that to the small intestine. I made a longitudinal incision on that surface equidistant from the mesentery so that the wound of the small intestine would correspond to the size of the wound in the large intestine, and approximated them with — Lambert stitch. There was no mesentery taken away. The wound was brought edge to edge. The abdominal

⁸ See page 269 of the Journal.

wound was then closed, the intestine with the suture being dropped back into the abdominal cavity. The patient made what would be called an uninterrupted and uneventful recovery, except that the record states that about three weeks after the operation when there had been normal dejections for some time, some fetid pus came from the wound with a fecal odor. There was no artificial anus, however, reformed, but the wound had closed entirely and it was only because the pus in close relation to the intestine produced the odor; and she was discharged from the hospital two months and a week after the operation, well. She lived a number of years, and died at the Cambridge hospital; and Dr. Gray, then the surgical interne, made the autopsy and sent me the specimen which was given to Dr. Whitney for an examination, and it was impossible to say from the looks of the intestine where the sutures had been passed.

About a year after this operation, when called to Lynn in consultation to see another case, I was asked, while waiting for the train, to see a man who had an artificial anus from gangrenous hernia, and to see whether anything could be done. I found this man in the condition in which all these cases are, but he was if anything more lamentable than many. He was lying in bed, and he had devised something which he had fitted to the side to catch the feces, otherwise he would have lain in a puddle of feces. His statement was that he rather die than go on living in that way. He came to the hospital and was operated on in the same way, and with perfect success, the intestine being dropped back into the wound; and I cannot say whether the wound was closed or not, but the recovery was uninterrupted, and he gained very rapidly in his general condition.

I did not hear Dr. Gay's paper, but Dr. Scudder in writing to me to know whether I would discuss the paper informed me that Dr. Gay proposed to consider five different methods of procedure in connection with gangrenous hernia: (1) Making an artificial anus. (2) Opening the sac. (3) Dividing the constriction and leaving the intestine *in situ*. (4) Resecting the bowel. (5) Leaving the patient alone.

Most of these points have been considered by the different speakers. It seems to me there are two points in which there should be no doubt whatever, and that is that an artificial anus should be established, that is, opening of the gut, and that the constriction should be divided. I think those two rules would hold good in regard to every case of gangrenous hernia. I can see no reason why the sac should not be opened when the constriction is divided, and it seems to me that it would be very much better in order to anchor the gut in such a manner that it could not escape back into the abdomen.

With regard to excising of the bowel, I think each individual case would have to be decided on its own merits at the time, and the manner in which Dr. Burrell put it, it seems to me, is such that we could all accept his statements with regard to it. I believe myself, however, that the making of an enterorrhaphy at the time is in nearly all cases unwise. There are few cases of obstructed bowel that would come to the condition of gangrene that are in a condition to undergo the protracted operation, and in the light of the number of most excellent results that have been obtained by the closing afterwards of the artificial anus left from such condition, it would seem wiser under those circum-

stances to leave enterorrhaphy for a later operation to be determined by the condition of the patient. Few can obtain, except by experiments upon animals, the rapid technique to enable them to suture the intestine. It is certainly a very nice operation to do properly, and many of the fatal results after such an operation are due to the faulty technique, and every one who has tried to suture the intestine recognizes the fact that at the mesenteric border it is very difficult to adjust the suture, and those who have had experience, it seems to me, always adjust those sutures first in order to feel sure that they have been properly placed.

I should say in regard to the return of the bowel to the abdominal cavity that I should be always against it in gangrenous hernia. I think it should be retained in the wound and an opportunity for a free discharge of fecal matter made.

With regard to leaving the patient alone, I should think it was a simple question whether the patient was in *articulo mortis*. I should say the patient should have the benefit of free opening and the relief of the constriction, because the relief of the constriction takes away a great deal of that shock which follows upon any constriction of the gut or the omentum. I think that every one who has had occasion to operate upon any hernia where the omentum has had to be tied off has felt that the shock to the system from the ligation of a considerable portion of the omentum in order to get rid of it, and to drop the pedicle back, is the source of the greater part of the shock during the operation. I have operated a number of times for the cure of large omental herniae where they were adherent, and where it was necessary to tie off a very large portion, and the shock of the operation has been to my mind mostly due to that, so that it seems to me that the patient should have the benefit at least of a temporizing operation making an artificial anus and relieving the constriction.

Dr. E. W. CUSHING: I should like to hear some discussion regarding the cases which are not exactly gangrenous herniae, but where the surgeon is called upon to decide whether the intestine still retains its vitality and should be returned. It is of great importance to know if the intestine can be returned at once, since recovery is much more rapid, and the necessity of a prolonged operation is avoided. I hoped to hear something in regard to diagnostic data which would enable one to decide that point. In a large number of cases the character of the bowel is extremely doubtful. I have seen cases returned which I thought had lost their vitality, and which did perfectly well. Other cases which did not seem to be dangerously affected were returned with disastrous results. It is a condition which I have found at times quite difficult to decide.

Dr. J. C. IRISH: I have never made the operation of resection of the intestine, for the reason, that, since that has become an established mode of practice, I do not know that I have seen a case of gangrenous hernia. The portion of intestine involved in gangrenous hernia I believe plays a very important part in the subsequent course after operation. In connection with that I recall a case I saw in consultation with a physician who had opened what he supposed to be a suppurating inguinal gland, and to his horror he found that he opened into the intestine. There was a large discharge of feces through that opening, and an artificial anus remained for a time, but finally feces passed by the rectum, and the man made a

spontaneous recovery. While usually it is the small intestine that becomes strangulated in hernia, still in this case and in others that recover in a similar manner, it is probably the colon that is involved.

Two cases that I have seen of gangrenous hernia, one in my own practice and one in consultation, were cases in which, when the operation was made, whether the intestine was gangrenous or not was doubtful. In these two cases the intestine was returned. In one case the patient died very soon after from septic peritonitis; and in the second case, some twelve days after the operation, the external wound being completely closed, with no drainage, feces appeared at the wound, and the patient, who had without doubt fecal extravasation into the abdominal cavity, went along for some two or three months, with the entire discharge escaping through the opening, and finally died of exhaustion.

Now the suggestion of Dr. Richardson to resect and to leave the wound open and pack with gauze to act as a drainage, in case of failure, would not leave the patient in any worse condition probably than exists in some of the cases of artificial anus. There is perfect vent for the discharge; and the fact, too, that even extravasation of feces into the abdominal cavity is not necessarily fatal, together with the hope of complete cure to the patient, instead of artificial anus, would lead me to believe that suture of the intestine is the wise procedure in all those cases where the general strength of the patient would admit of so long an operation as that of resection and suture.

DR. M. H. RICHARDSON: I looked upon this subject as one of very great practical interest. I do not agree with those who say that no cases of gangrenous hernia are suitable for excision and suture. No one would think for a moment of performing the operation of anastomosis or of resection and suture in a very feeble patient; but in those not infrequent cases with a history like that of the patient whom I have just exhibited, and like the case of successful resection and suture which I reported some years ago, where the strength is good and the general condition satisfactory, — in such cases there is no good reason why the comparatively short operation of resection and suture or of intestinal anastomosis should not be performed. Up to two years ago the death-rate in intestinal resection for gangrenous hernia was about fifty per cent. I do not think that the mortality is any less than this by any method of treatment; but there is no doubt, I think, that this percentage of recovery is too high, for the obvious reason that more successful cases are reported than unsuccessful. The mortality depends largely upon the time essential to the proper performance of the operation. If we select either intestinal anastomosis or resection and suture, or even the comparatively rapid procedure of artificial anus formation, in all these operations so much time is necessary as seriously to endanger the life of a very feeble patient. In the latter operation — the formation of an artificial anus — it is necessary to sew the cut ends of the bowel into the wound so securely that there will be no danger of giving way, and so neatly that there will be no extravasation into the abdomen; in other words, you have a quite prolonged operation and one that cannot safely be resorted to upon a patient *in extremis*. In such serious cases simple excision of the gangrenous bowel and enlargement of the ring seems to be the only justifiable procedure, but even this operation is not free from the danger of infection through the incised

ring. I certainly do not differ materially from the opinion expressed by every one this evening when I advocate excision of the gangrenous portion of bowel and immediate closure, either by anastomosis or by end-to-end suture, in those cases where the patients are young, in good or fair condition, and presumably with good powers of recuperation. By simple incision of the sac and palliative treatment we not only do not avoid great present danger, but we leave the patient to undergo the risks of subsequent attempts at closure, to say nothing of the menace to life and discomforts of constant fecal escape in the meantime. As I stated two years ago in Washington, I believe now that the combined dangers of two operations are as great or even greater than the dangers of one radical operation. Now, in the case of the young man whom I show tonight, at the second operation the danger from extravasation of feces into the abdominal cavity was surely as great as it would have been if the operation had been performed at the time of the original strangulation. There was quite as much danger of infecting the abdominal cavity from the unclean condition of the parts as at the time when the sac was filled with gangrenous contents. Therefore, the danger of infection being practically the same at both times, there is no valid reason why the radical operation for restoring the intestinal canal should not have been done in the beginning, provided his strength was sufficiently good. This patient certainly has been twice exposed to the gravest danger.

I am very glad to hear Dr. Cabot say that he believes the end-to-end suture is better than anastomosis. I have long been of that opinion, although having no experience with the latter operation. The first objection to circular enterorrhaphy is that there will be subsequent constriction. Dr. Porter's two cases reported some years ago show that this is not the fact. In one of these cases the autopsy, performed some years after the operation, showed no diminution whatever in the intestinal calibre. The history of my first case, which I followed until her death from cancer of the uterus, showed that there was no obstruction, and in the present case there is none. Nor in any of the cases with which I am familiar has there been any subsequent constriction, early or late.

In comparing the time consumed by the different methods, I do not believe that intestinal anastomosis properly performed is substantially a more rapid procedure than circular suture. In the one case it is necessary accurately to sew up the two open ends of the intestine, to incise and to apply the plates, and in some cases to add a line of accessory sutures. End-to-end suture does not require more than twenty minutes for its application after the bowel has been excised. I do not speak from personal knowledge of the technique of intestinal anastomosis, but from my experience with end-to-end suture I must say that there can be no more beautiful operation in surgery than the rapid and neat approximation of bowel ends when brought together by the interrupted Lembert method.

Another and very important reason for establishing continuity of the bowel at once is the fact that the small intestine, high up, may be the part involved, and the formation of an artificial anus would result in death from inanition. It is always easy to recognize the large intestine, but it is very difficult, if not absolutely impossible to tell what portion of the small intestine is involved.

My first case, which was fatal although the joint healed, took an hour for the performance of resection and suture, but the actual closure of the intestine did not consume more than twenty or thirty minutes. In the second case, which was successful, the whole operation was fifty-five and the suture between twenty and thirty minutes. The last operation took an hour, but the greater part of the time was occupied in finding the ends and in trying to approximate them so as to make an anastomosis.

In considering results we must bear in mind that the mortality is necessarily large in all methods of treatment, even in those cases which have been reported this evening, where death has followed the formation of an artificial anus, and that the constitutional effects of prolonged strangulation are in themselves extremely grave.

The method which I have described, and have employed in my last two cases of intestinal suture obviates one of the greatest dangers of the end-to-end method. I refer to the application of gauze to the line of suture. By this method I think there is little or no danger of a general peritonitis from extravasation. I have found in operations for appendicitis, in intestinal resections, cholecystotomies, and in laparotomies generally that adhesions are formed and the general peritoneal cavity shut off from the line of gauze very quickly. I have noticed that the fibre of the gauze is impressed almost immediately upon the peritoneum, and it apparently has some irritating effect. If the stitches do give way, we have not only the abdominal cavity shut off but an excellent drain provided. There is no danger of a permanent sinus, for we have still the greater part of the stitches holding. At most a small fistulous channel may remain precisely as is seen after excision of the appendix. The escape of feces may last for two or three weeks, as I have observed time and again in operations upon the vermiciform appendix. Sooner or later the faecal discharge ceases.

I think the subject is a very important one, and I have often been in doubt as to the proper method to pursue in a given case. I believe that the best method to pursue in a case of gangrenous hernia, where the patient is in fair condition, is at least to give him the benefit of a free incision with relief to the ring and the formation of an artificial anus. If everything is favorable as to surroundings and assistants, and the patient's condition is good, I should favor immediate excision of the gangrenous portion of the intestine with the end-to-end interrupted suture of Lembert.

Dr. C. B. PORTER: I think Dr. Richardson misunderstood me. I did not say that I thought that in no case of gangrenous hernia should an enterorrhaphy be done at the time. I said I thought that in nearly all cases where the intestine had been down long, if they are subjected long enough to pressure to produce the gangrenous condition, the patient was not in a condition to warrant that procedure at that time. I do not think Dr. Richardson can recall many cases of gangrenous intestine where there has not been great shock and great prostration and usually pretty marked collapse. That is the ground that I put my objection to the immediate enterorrhaphy on.

He speaks about the end-to-end suture, and if it might be allowed. I will just mention a case of end-to-end suture which I did last year under what might be considered very favorable circumstances. An old lady in the sixties had a very large abdominal tumor

which was very adherent and which I removed. There were two very large lobes, closely placed to each other, and in between them, at the bottom of the deep sulus, the intestine was attached, and it was not where I could see it, and in trying to lift out the tumor the intestine was torn in such a way as to require the resection of the whole lumen of the intestine. That was done, and the bowel closed end to end by fifteen silk sutures placed in the ordinary Lembert method, and then the continuous suture around beyond this. The patient made an uninterrupted recovery, and was discharged from the hospital seven weeks and two days after the operation. The operation lasted three hours.

Dr. Richardson referred to a statement that no cases of end-to-end suture had been reported where obstruction occurred. I would state that I mentioned one.

DR. BURRELL: There is one thing which has come to my mind, that in these intestinal resections that have been reported the Lembert suture has been used almost exclusively in all the cases; and I have wondered why approximation plates or segmented rings or some contrivance of that description had not been used by the gentlemen. I should like to ask Dr. Porter the length of time it would take for an average enterorrhaphy.

DR. PORTER: I learned the operations upon animals before these plates were used at all, and I feel rather at home with the operation. Perhaps that is one reason why I prefer it. I have the decalcified bone plates of all sizes in my office, but never had occasion to use them. I have never timed myself on the operation. I should think it would be approximately twenty to twenty-five minutes.

DR. CABOT: I should like to recall one case of somewhat allied condition. This was a case of gangrene of the sac, which I reported some years ago. I operated upon an old German or Russian woman for strangulated hernia, incised the constriction and returned the hernia. I tucked the sac back into the ring and brought the pillars of the ring together over it. The patient was not in a condition to stand a long operation and bore it badly. She came out of the ether well, and did not vomit for the first twelve hours, but after that began again to vomit and went on doing well, until on the second day after the operation I decided to open the wound again to ascertain whether there was not still some internal strangulation. I had recently had such a case and was on the lookout for it, and this continued vomiting seemed to warrant the belief. I opened the abdomen. There was no strangulation of any sort.

The bowel was perfectly free. The sac looked rather grayish, and I placed it well outside of the abdominal cavity, opening the original wound. The patient came out of the ether that time in better shape than before, and went on to an uninterrupted recovery. A large portion of the sac sloughed away later. I speak of this as something worth thinking of in some of these cases where there has been a good deal of pressure, particularly where there has been much taxis, as a reason for not always adopting the stitch of Mr. Macewen.

DR. GAY: In regard to the time, I think my first operation took an hour, the second operation forty-five minutes.

Dr. Porter made one remark that makes me suspect that perhaps he thinks somebody has recommended that a distinctly gangrenous bowel should be returned

to the peritoneal cavity. I have not heard any such recommendation as that made. It is the doubtful cases we sometimes put back, not the gangrenous ones.

DR. BRADFORD reported

THREE CASES OF SEPARATION OF THE EPIPHYSIS AT THE HEAD OF THE FEMUR.⁴

THE NEW YORK ACADEMY OF MEDICINE.
SECTION ON ORTHOPÆDIC SURGERY.

STATED Meeting, January 15, 1892, SAMUEL KETCH, M.D., Chairman.

THE DISAPPEARANCE OF LARGE PSOAS ABSCESSSES.

DR. HALSTED MYERS presented a case of lumbar Pott's disease, to illustrate the disappearance of very large psoas abscesses without material interference with the general health during the process.

In this case, which had a strong family tendency to tuberculosis, the abscess appeared early, had gradually increased in size; but after an attack of measles it had become much larger, so as to fill both iliac fossæ, and form pouches in both inguinal regions, as large as a man's fist. At this time the liver was slightly enlarged, but there never has been a trace of albumen in the urine. Eight months later, though still anemic, the child felt well, had an excellent appetite, and the liver had regained its normal size. Absorption was rapidly progressing.

At present the child has a temperature ranging between 98.4° and 99.6, and has a few enlarged cervical glands; but he plays hard all day, has a good appetite, and feels well. The abscesses have almost entirely disappeared, and recovery seems assured.

DR. NEWTON M. SHAFFER said that he had seen this case from time to time, and could testify to the large size of the abscesses. This case would certainly have been considered by some of their colleagues, a fit one for a operative interference, notwithstanding that such an operation would necessarily have proved rather serious, on account of its extent. As usual, under proper mechanical treatment, the abscesses had disappeared.

DR. V. P. GIBNEY said that, in connection with this subject, he desired to report an instructive case. About fifteen years ago, a boy was brought from the West to the hospital, with disease of the lumbar spine. The brace at that time in vogue at the hospital was applied, and the child did well for two or three years, when he experienced some pain in the left thigh, and a tumor appeared in the left iliac fossa. The speaker had advised the systematic use of hot-water douches over the parts, and the result of this treatment was considered at the time to be quite brilliant. He had only just learned the sequel of this patient's history. Shortly after the disappearance of the abscess from the iliac fossa, and while still wearing the spinal support, an elongated tumor made its appearance in Scarpa's space, and then burrowed down until it nearly reached the inner condyle. There was then some redness and tenderness, so the hot douches were resumed, with the effect of causing an entire disappearance of the tumor. Nothing further occurred until several years afterward, when after a fall or strain of some kind, a large and tender tumor made its appearance very suddenly on

the outer side of the thigh, at the junction of the middle and upper thirds. This was accompanied by pain and considerable constitutional disturbance, and a surgeon incised the abscess, removed some bone detritus, and irrigated the cavity. Since then, although the sinuses have been washed out daily with bichloride of mercury solution, and afterwards with peroxide of hydrogen, and then dressed with sublimate gauze, they have been discharging pretty constantly, and there have been occasional symptoms of sepsis. The remnant of the sac can still be felt in the iliac fossa. The tumor which appeared on the outer side of the thigh was probably nothing more than the old abscess deflected by the concussion of the fall.

DR. GIBNEY said that he had narrated this case, because it was one of those in which the abscess had disappeared under what was considered to be good treatment, and yet he was not entirely satisfied with this treatment. He had seen many cases in which the abscess had disappeared in this way, and he was glad when this occurred, but sometimes he could not help feeling that it might be better if he could, under thorough antisepsis, remove this pus by a surgical operation, and so relieve the patient from this constant menace.

THE USE OF IODOFORM IN THE LOCAL TREATMENT OF STRUMOUS JOINT DISEASES.

This was the title of a paper by DR. J. D. BRYANT. In this paper, the author used the terms, "strumous disease," and "tuberculous disease" synonymously. For practical purposes, the products of tuberculous joint disease, may be said to be located in the joint cavity and its lining membrane, and in the peri articular tissue, associated with this membrane. The rice and melon seed bodies in these diseased joints, are often infected with the tuberculous agents. In the present paper, the author excluded from consideration, disease of the integument, and of the immediate subcutaneous tissues.

The preparations of iodoform which had been used by the author were ten per cent. solutions with ether or glycerine. The ethereal solution was easily obtained in an aseptic condition, it flowed freely through needles of small calibre, and by its rapid diffusibility, quickly deposited the iodoform upon the disease products. But this very property of rapid diffusibility made it objectionable on account of the liability of producing constitutional effects, and because of the irritation produced by the fluid, which made the injections extremely painful, and often gave rise to circumscribed abscesses. A solution of iodoform in sterilized glycerine or oil had the advantage of not producing these unpleasant constitutional effects, and of not being painful when injected, but on account of its viscosity, it was necessary to employ needles of large calibre. It was well to remember that all iodoform solutions are prone to undergo chemical decomposition, especially when nearly saturated, or when exposed to sunlight. Camphor has the property of increasing the solubility of iodoform in these fluids, so that a saturated solution of camphor in olive oil will dissolve six per cent. of iodoform.

No definite rule can be laid down as to the amount of iodoform which can be injected without danger of producing constitutional effects; thus one and a half grains have been known to give rise to these symptoms, while in other cases, no such result has followed the introduction of one hundred and fifty grains. It is

⁴ See page 212 of the Journal.

generally considered that thirty grains of iodoform may be injected, but the difference of action of the ethereal and the glycerine solution must be borne in mind.

The author then spoke of the different manifestations of iodoform poisoning, those cases being considered the most dangerous in which there was a rapid and compressible pulse, either with or without fever. Then the presence of iodoform in the human system is evidenced by a disagreeable taste; the introduction of a silver piece into the mouth, will immediately develop a garlic taste, which, according to Poncet, is characteristic of the presence of iodoform. Another test is the production of a canary-yellow color when calomel is mixed in the saliva.

The author related in detail the histories of two cases, to illustrate the action of the iodoform in the treatment of joint disease. In the first one, the patient, aged eighteen, was admitted to Bellevue Hospital on February 17th, 1891, with a history of having suffered from disease of the knee-joint for three years, during which time, he had been treated in various ways without benefit. The synovial cavity was greatly distended with fluid, there was no special tenderness, and no increase in the temperature of the joint. There was much relaxation of the ligaments, and lateral motion on hyperextension. Walking did not cause pain, but there was so much relaxation of the lateral ligaments, that locomotion was impracticable without confining the joint with a bandage or splint. On February 21st, the joint was opened by a free incision, and its cavity thoroughly irrigated with a 1: 2000 solution of bichloride of mercury. Numerous melon-seed bodies were evacuated, and the wound then closed. The wound healed by primary union, and the joint was diminished in size, but the previously over-distended soft parts remained fleshy, and the relaxed ligaments made the joint very insecure. On April 1st, the joint was opened in two places, at the site of the former incision, and at the outer side of the quadriceps tendon, so as to lead directly into the outer pouch of the upward prolongation of the synovial cavity. After a thorough irrigation with 1: 2000 solution of bichloride of mercury solution, and the complete removal of numerous "rice-seed" bodies, the cavity was irrigated with a ten per cent. ethereal solution of iodoform, and the wounds closed as before. Primary union occurred without reaction. A portion of the synovial membrane was removed at this operation, and was sent to Dr. Briggs, who reported that there was no doubt about its being involved in the tubercular infection. From this time until May 1st, the knee diminished in size, and increased in stability, yet the latter was not sufficient to render the joint secure. On May 9th, a small quantity of fluid still remained in the joint, and as the patient was anxious to leave the hospital, two ounces of a ten per cent. solution of iodoform in glycerine were injected directly into the joint cavity. There was no reaction, and after four or five days rest in bed, the patient was allowed to go around the ward, and on June 16th, he was discharged. There had been no pain, tenderness, or effusion for two weeks prior to his leaving the hospital. Should a similar case come under his observation, the author said that he would prefer to open the joint at once, in two places, clean out the cavity by irrigation and manipulation, and after perfect union had been secured, inject into the cavity, two or three ounces of a ten per cent. solution of iodoform in sterilized glycerine or oil.

In a second case, one of old knee-joint disease, attended with considerable flexion of the leg and subluxation of the head of the tibia, occurring in a man, twenty years of age, iodoform injections were begun after other recognized methods of treatment had failed to produce any noteworthy local improvement. The case was under the care of Dr. Gardner, of this city.

Eight drops of a twenty per cent. solution of iodoform ether were injected at each of three separate points of greatest tenderness, into the deepest tissues, and perhaps some portion into the joint itself. Great pain was produced at the site of the injection, followed by numbness of the limb, and persistent nausea for twelve hours, and, as the same symptoms followed a second injection, it was decided to substitute a twenty per cent. solution of iodoform in glycerine. This latter preparation caused less pain in the limb and no systemic disturbance. The injections were repeated every two or three days. At the end of thirty days, the joint was free from pain and swelling, the doughy feeling was gone, there was voluntary motion, and considerable weight could be borne by the limb. His general condition also kept pace with the local improvement, and at the present time, the limb is nearly as strong as the other; there is considerable motion, so that the patient can walk on it without artificial aid. There can be no reasonable doubt of the tuberculous nature of the disease of the joint in this case, nor of the curative effects of iodoform.

DR. A. B. JUDSON had failed to see the necessity or desirability of using iodoform in joints which are under mechanical treatment. In children thus affected, local medication may be ignored in favor of general treatment. He believed that the trouble is not so much a local fault, as a failure for some reason or other, of the system to arrest the morbid action, and repair the damage already done, and the system, rather than the affected part, should receive most attention. Mechanical treatment is a local application, but its indirect action is of the utmost importance in relieving pain, permitting sleep, facilitating locomotion and promoting general well-being. It prevents the injurious effects of habitual trauma and provides for ultimate symmetry and ability. Beyond this roborant and reconstructive treatment, general medication is in order, reinforced by hygiene and an abundance of rich and wholesome food, in which cream and other forms of animal fat should be in excess. He believed the effects thus produced leave no room for the administration of antiseptics and purgatives.

DR. ROYAL WHITMAN said that he was surprised to hear the previous speaker express doubt as to the influence of iodoform on tuberculous processes, for, it was not a matter of opinion, but of record: Bruns, Krause and other investigators had shown that the membrane of tuberculous abscesses ordinarily consists of four layers: (1) an outer layer of thick porous tissue; (2) a layer of spindle cells in a state of active proliferation; (3) actual tuberculous granulations, and (4) necrotic and degenerated tissue. The two inner layers contain the tubercle bacilli. Under the iodoform treatment, it was found that healthy granulations sprang from the spindle-cell layer, the bacilli disappeared and the tuberculous granulations and inner layer were converted into a fluid, which might be absorbed or withdrawn with an aspirator. Arens, in a recently reported series of 255 cases of tuberculous disease of various joints, states that under the iodoform

treatment, forty per cent. showed very marked improvement. The most favorable cases were those of disease of the wrist and elbow. Trendelenburg had given up the use of the etheral solution in his clinic, because of the pain produced. Instead, he uses a twenty per-cent. solution of iodoform in oil, injecting about one teaspoonful at intervals of eight days. Krause uses a larger quantity, thirty to eighty cubic centimetres, injecting at intervals of three weeks. Bruns states that eighty per cent. of all abscesses may be made to disappear by the use of iodoform, and the specific action of this drug on the tubercle bacillus, seems to be very generally-recognized. Trendelenburg is now using oil and iodoform at a temperature of 100° C., with the object of making a solution of the iodoform in the oil, and of securing its deposition in a more finely divided state.

DR. SAMUEL LLOYD said that he had seen very remarkable results in his clinic, following the use of injections of iodoform emulsion, both in joint difficulties and in tubercular adenitis; in fact, in the latter class of cases, they acted so satisfactorily that they had been used almost to the exclusion of operative measures. In some cases where tubercular deposits had been found in the lungs, the change was very decided after the injections, especially when these were pushed up to the point of producing constitutional effects. In one or two cases where operative procedures had been undertaken, and secondarily, injections had been used on a recurrence of the disease, the improvement was much more rapid than after the first operation when the iodoform was not employed. When using the iodoform injections in abscess cavities, the results had not proved good until the cavity of the abscess had been washed with hot water, or with some antiseptic solution. It is advisable then to inject the emulsion up to the point of causing some distension. Dr. N. Seun had had a similar experience; and in his recently published article on this subject, he says he uses weaker solutions of iodoform, but in larger quantities.

DR. R. H. SAYRE said that in using these injections, he had felt the necessity of employing the iodoform in a more finely divided state, and therefore, he thought it was an advantage to use the heated oil. He recalled two cases of suppurating ankle-joint disease, one of which had been treated by injections of iodoform, and the other by injections of aristol. They had done equally well, and after about two months of treatment, the evidences of inflammation had entirely disappeared, and there was no pain or tenderness about the ankle. A splint had been applied to take off the weight of the body. In a case of tubercular inflammation of the thumb, he had obtained a good result from the injection of a ten per cent. solution of iodoform and likewise in some abscesses.

DR. H. L. TAYLOR said that he endorsed what Dr. Judson had said as to the value of mechanical treatment, and yet welcomed the method presented in the paper. His experience with iodoform in a few cases, had convinced him that it had a specific action on tubercular tissue. One of his most striking cases, was that of a typically tubercular subject, a youth of seventeen years, who had been for some time under observation of Dr. Da Costa for suspected pulmonary disease. He had been hobbling about without crutches, in spite of advice, for about one year after the development of symptoms of tarsal disease, before he came under the speaker's care. He was made to use crutches, and the

foot was immobilized with an apparatus. After some months, a sinus having appeared, on the advice of Dr. Abbe, injections of an etheral solution of iodoform into the joint were begun. He could honestly say that the entire appearance of the affected parts was changed after one injection, and the subsequent progress of the case to complete cure, although slow, was steady. He had also used the iodoform emulsion in sinuses about joints, and he believed that this treatment produced beneficial effects independently of its antiseptic action.

The CHAIRMAN said that about two years ago, while visiting the clinics in Germany, he had seen a good deal of this treatment with the etheral solution of iodoform, and he had been impressed with the great frequency of symptoms of iodoform poisoning, and with the general disregard of mechanical treatment shown by these surgeons. Still, he believed that in these iodoform injections, we had a valuable adjunct to mechanical treatment, and one which had not been sufficiently tested by American orthopedic surgeons.

DR. BRYANT, in closing the discussion, said that he had not had the slightest idea of substituting the iodoform injections for mechanical treatment, but he had thought that it could not fail to be a valuable adjutant to this treatment, on account of its well-known influence upon the tubercle bacilli, and because the injections could be so easily made. In the case of knee-joint disease which he had described, there the rice and lemon seed bodies were in such large numbers, he did not believe that mechanical treatment alone would have cured the case; in fact, the patient had had this treatment and had not been benefited by it.

Recent Literature.

Ptomaines, Leucomaines and Bacterial Proteids; or, the Chemical Factors in the Causation of Disease.
By VICTOR C. VAUGHAN, Ph.D., M.D., and FREDERICK G. NOVY, Sc.D., M.D. Second edition, revised and enlarged. Philadelphia: Lea Brothers & Co. 1891.

This book is rewritten from the old edition of three years ago, and, being brought up to date, is a material improvement on the first. Ptomaines are defined as those chemical compounds which are basic in character and are formed by the action of bacteria on organic matter; while leucomaines are those basic substances which result from tissue metabolism in the body; the bacterial proteids are those formed by the fermentative action of bacteria. It will be seen, therefore, that the difference between a ptomaine and a leucomaine is simply one of origin, and does not indicate any fundamental difference between the two groups.

A brief chapter is devoted to the history of the bacterial poisons, and then a *résumé* of some poisonous foods, with the symptoms produced by them, is given. The list includes mussels, fish, sausages, ham, meat, cheese, milk, ice cream and bread. Cases of poisoning by mussels and fish are included in which it is not at all clear that the poison existed in the food, and judging by the more recent reports were probably due to bacterial infection. Their inclusion, however, only increases the value of the book.

The fourth chapter is devoted to a general consideration of infectious diseases, and gives very much the

position held by all intelligent workers, while in the next the poisons of particular diseases are treated. The list includes anthrax, Asiatic cholera, tetanus (for which he recognizes two germs, that of Nicolaier and that of Kitasato), tuberculosis, diphtheria, suppuration, the summer diarrhoeas of infancy and typhoid fever. The summer diarrhoeas are rightly attributed to many kinds of bacteria, and the credit for this discovery is given to Vaughan, Barker and Escherich. The position held in regard to typhoid fever is peculiar to the authors, namely, that the Eberth bacillus, as found in the spleen after death, is an involution form of any one of a number of germs which are found in certain waters.

The latter, and by far the larger, part of the book is devoted to the chemistry of the subject. The methods of work are outlined, and the importance of some of the poisons to the medico-legal examiner are pointed out. Fifty-nine ptomaines and eighteen leucomaines are considered in detail, among which is to be found the old acquaintance of many, xanthine. The last chapter is devoted to auto-infection, while last, but not least, there is a most extensive bibliography of the chemistry of the subject.

As a whole, the book is clearly written, well arranged and comprehensive, but gives one the impression of underrating the knowledge possessed by all bacteriologists. The book will be found a great convenience to all who desire to form a measure of our present knowledge of the difficult subject of bacterial and somatic poisons.

Diphtheria: Its Natural History and Prevention. Being the Milroy Lectures Delivered before the Royal College of Physicians of London, 1891. By R. THORNE THORNE, F.R.C.P., F.R.S., London, assistant medical officer to Her Majesty's Local Government Board. London and New York: Macmillan & Co. 1891.

The author's position under the Local Government Board and his work in connection therewith are a guarantee of his fitness to deal with the subject which he chose for the Milroy lectures of 1891. A final chapter consisting of eighteen conclusions, sums up the author's views. From among these "conclusions" we extract the following: (2) During the past twenty years there has been a progressive increase in the rate of mortality from diphtheria in England and Wales; (12) There is reason to believe that attacks of so-called "sore throat" exhibit under certain favoring conditions a "progressive development of the property of ineffectiveness," culminating in a definite specific type which is indistinguishable from true diphtheria.

Surgery. A Practical Treatise with Special Reference to Treatment. By C. W. MANSELL MOULLIN, M.A., M.D. Oxon. Fellow of the Royal College of Surgeons, Surgeon and Lecturer on Physiology to the London Hospital, etc. Assisted by various writers on special subjects. With five hundred illustrations, two hundred of which have been made for this work from special drawings. Philadelphia: P. Blakiston & Co., 1012 Walnut Street. 1891.

The book is divided into three parts. Part first includes the general pathology of surgical diseases; part second that of injuries; and part third the diseases and injuries of special structures and organs. The specialists in their respective departments, have con-

tributed satisfactory chapters, although it may be questioned whether it is wise to introduce into a treatise on surgery the diseases of the eye. The volume as a whole is quite satisfactory as a guide to the general practitioner. It, however, is far from the ideal. Many of the cuts are imperfect, and express but little. There is a want of appreciation of the relative importance of the subjects dealt with. For example, so important a subject as anaesthesia, including a consideration of local and general anaesthesia, the administration of nitrous oxide, ether, chloroform and the A. C. E. mixture, is dismissed in two pages and a half; while the relatively unimportant subject of spina bifida occupies four pages and a half, and lateral curvature of the spine occupies six pages and a half. Very few references are given to authorities quoted, and while this is excusable, yet it is not quite satisfactory. However, the reader will find many subjects treated with a commendable attention to important details. The chapter upon fractures is valuable, and the author's conservatism is worthy of careful consideration.

Lectures on Tumors from a Clinical Standpoint. By JOHN B. HAMILTON, M.D., LL.D., Professor of Principles of Surgery and Clinical Surgery, Rush Medical College, Chicago; and in the Chicago Polyclinic; etc. For the use of Students. Physician's Leisure Library. Detroit, Mich.: George S. Davis. 1891.

This little book presents the lectures by the author, as they were taken down by a stenographer. The author's aim was to impart "the current information in a form intended to fix it in the memory." There are a few interesting cases recorded, but the book, as a whole, is not one that we can commend. Many broad statements are made, and, unfortunately, typographical errors are frequent.

Surgical Bacteriology. By N. SENN, M.D., Ph.D., Professor of Surgery, in Rush Medical College, Chicago; and in the Chicago Polyclinic; Attending Surgeon to the Milwaukee Hospital, etc. Second edition, thoroughly revised. Philadelphia: Lea Brothers & Co. 1891.

The first edition of this book was quickly exhausted, and in the second edition "the author has aimed to add new facts illustrative of the relations of pathogenic micro organisms to the various surgical lesions, and eight new illustrations have been inserted in the text, descriptive of microbes, not illustrated in the first edition."

The material for this book has been obtained from the current literature, and it embodies the best work of the leading men. The book has been divided into chapters, which will be a matter of convenience to the reader. The index of subjects and the index of authors are of considerable value in referring to various subjects. The book, as a whole, is an excellent presentation of the literature of surgical bacteriology. The plates are extremely valuable, and serve to illustrate the text in a very satisfactory manner. To any one desiring a general idea of surgical bacteriology we can commend this volume.

THE new hospital at Antananarivo, the capital of Madagascar, was opened by the Queen of Madagascar recently. It is sustained by the Society of Friends of Great Britain.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, MARCH 3, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

283 WASHINGTON STREET, BOSTON, MASS.**

**THE PUBLIC HEALTH IN MASSACHUSETTS:
TYPHOID FEVER AND THE TYPHOID BACILLUS.**

The Twenty-second Annual Report of the Massachusetts State Board of Health, for the year 1890, comprises the general work of the Board and papers upon special sanitary topics, including a report to the legislature upon water-supplies and sewerage, with a statement of the advice of the Board given under the law of 1888; examinations of water-supplies and rivers; suggestions as to selection of sources of water-supplies; report of food and drug inspection; summary of weekly mortality reports; statistics and observations on the growth of children, by Prof. H. P. Bowditch; typhoid fever in its relation to water-supplies; health of towns.

The six cases of small-pox which occurred in the State during the year, with one death, were investigated and at once controlled, such cases as occurred in other States and in Canada being also reported; severe local epidemics of diphtheria revealed, besides infection, bad sanitary conditions and, in one case, a probably infected milk-supply; a special investigation indicated an increased number of deaths from hydrophobia and a wider prevalence in the State; two cases of trichinosis, a rare disease with us, were reported; one noxious trade, for the manufacture of Paris-green, was so regulated as to abate the nuisance.

Advice regarding water-supplies was given in 17 cases; in 17 also with reference to sewerage and sewage-disposal. Three hundred and forty-five pages of the report are given to a minute investigation and report upon the various questions affecting water-supplies and sewerage and the purification of sewage and of water by filtration. The facts determined and the observations thereupon maintain the high standard of scientific and practical value with which we have become familiar in previous reports of the Board.

Including milk, 5,585 samples of food were examined, of which 1,814 were found impure or not conforming to the statutes; of 3,236 samples of milk,

1,858 were above the standard and 1,378 below, or adulterated; in 400 samples of drugs, the percentage of adulteration was 1.87.

The weekly reports of mortality, although not complete, have been distributed to boards of health and otherwise, thereby furnishing an important index of the prevalence of disease in the several parts of the State.

Mr. Mills, the distinguished engineer, a member of the Board, contributes a most important study of the excessive death-rate from typhoid fever in Lawrence and Lowell.¹ For the twelve years ending in 1889, those two cities had average annual typhoid death-rates of 8.33 and 7.63 for each 10,000 inhabitants, as compared with an average of 4.62 in the 28 cities of the State. In the year ending April 1, 1891, the rate in Lawrence, with a population of 45,000, was 17.33; and in Lowell, 19.23, with a population of 78,000. There was at the same time no noteworthy increase in deaths from typhoid fever in the other cities and towns of the State.

In Lowell the cases were very generally distributed throughout the city, the numbers following nearly the density of the population, all being supplied by the city water. The cases found in Lawrence were all within the area provided with water from the city water-works, and they were proportionately more numerous near the reservoir than at a distance from it.

The fact was discovered in November that the water-supply of Lowell was contaminated by faeces of typhoid-fever patients discharged into Stony Brook, only three miles up stream from the intake of the Lowell water-works, and in a very few weeks after there was a rapid increase in the number of deaths from typhoid fever in the city. Six weeks later there was an alarming increase in the number of deaths from typhoid fever in Lawrence, the water-supply of which is drawn from the Merrimack River nine miles down stream from the point where the Lowell sewage enters the river. In December the typhoid fever bacillus was found in water from the service-pipes in Lawrence.

The temperature of the river-water in November was from 45° to 35° F.; the distance from the sewers in Lowell to the intake of the Lawrence water-works is nine miles, and the time for the water to pass from the sewers to the intake was at that time less than eight hours. Entering the reservoir the same day, the water would reach the outlet and enter the service-pipes within ten days—most of it within a week. It would then be distributed over the city, in the portions near the reservoir, in about one week from leaving the sewers of Lowell, and in more remote parts of the city in about two weeks.

To prove whether typhoid fever germs would survive in the Merrimack River water, when at the low temperature of the month of November, long enough to pass from the Lowell sewers to the service-pipes in Lawrence, a series of experiments was made by the

¹ For Epidemic of Typhoid Fever in Lowell, by Prof. W. T. Sedgwick, see Journal, vol. xxiv, pp. 397, 426.

Board by inoculating water from the service-pipes with typhoid fever germs and keeping the water in a bottle surrounded by ice, at as near freezing as practicable, for a month, and each day taking out one cubic centimetre and determining the number in it of typhoid fever germs. The number constantly decreased from 6,120 the first day, 3,100 the fifth day, 490 the tenth day, 100 the fifteenth, to none on the twenty-fifth. The experiment clearly showed that typhoid bacilli from the sewers in Lowell may live in winter to enter the reservoir of the Lawrence water-supply; that the numbers will decrease in the reservoir; that a considerable portion will live to enter the service-pipes, and that this portion will decrease as the water proceeds in the pipes across the city — a fact which apparently explains the reason why much the larger number of cases of typhoid fever were in parts of the city near the reservoir; but that some germs survived the passage through the pipes was proven by their being found in water drawn from the service-pipes, in December, at the Experiment Station, across the city two and a half miles distant from the reservoir.

It was found, by the inquiry, that in general in the cities of the State the death-rate from typhoid fever has been greatly reduced by the introduction of pure water; that in one city (Holyoke), where there was not such a reduction, a portion of the people used, for drinking, water from canals or from wells subjected to serious pollution by sewage, and that the deaths from typhoid fever are much more frequent among that portion of the community which uses the contaminated water than among others.

The only two remaining cities, which have not diminished death-rates from typhoid fever after the introduction of water-supplies, receive their supply from a river polluted by sewage. The season in which typhoid fever prevails in these two cities is later than in other cities, and in the lower city on the river later than in the upper city; also in the lower city at a season when other places are nearly free from the disease, and when it would be prevalent if produced by the sewage of the upper city. Further, during the greatest prevalence of typhoid fever in the upper city, when the water of the river which passed the upper city and received its sewage had reached the service-pipes of the water-supply of the lower city, and there was the greatest prevalence of the disease in the lower city, typhoid fever bacilli were found in water taken from the service-pipes.

The wisdom of the legislature is shown in their financial support of the Board, the general expenses for the year having been \$9,871.01; for food and drug inspection, \$10,112.39; water-supply and sewerage, \$25,161.46.

THE OPENING OF THE LANGENBECH HAUS in Berlin will take place formally this spring during the annual meeting of the German Surgical Society. This is the building which has been erected as a place of meeting of all the medical societies in Berlin.

HERTWIG'S THEORY OF IMMUNITY.¹

THE theory of immunity recently propounded by Prof. Oscar Hertwig, the eminent anatomist and embryologist at Berlin, is especially worthy of note, not only because of the source from which it proceeds, but because it is an ingenious attempt at mediation between the contesting cellular and chemical hypotheses. Hertwig takes his stand upon the highly important discoveries of Pfeffer, Stahl, Gabritschewsky and others, regarding the influence of various chemical substances upon micro-organisms.

The distinguished plant physiologist Pfeffer, as is well known, found that certain chemical substances soluble in water exert an influence, part attracting and part repelling, upon freely motile plant or animal cells such as infusoria, spermatozoa, bacteria, leucocytes and their like. This phenomenon of "chemotropism," or "chemotaxis," is positive if the organisms advance towards the place from which the chemical stimulus proceeds, negative if they retreat from it. Malic acid in high dilution, for example, exercises a generally positive chemotropic effect, chloroform, a negative. That these terms "positive" and "negative" have only a relative value is shown by the fact that while a very weak solution of malic acid will attract motile organisms towards the capillary tube in which it is contained, a stronger solution — five per cent. — will actively repel the organisms. That is to say, the positive effect becomes a negative one as a result of the concentration of the chemical substance.

Furthermore, to continue with the example of malic acid, if the organisms are *ab initio* in a solution containing malic acid, a stronger solution of that acid will be required in order to attract them than is the case if they are in pure water. A solution of malic acid of sufficient strength to attract organisms from pure water will have no effect upon organisms already immersed from the start in dilute malic acid. On the other hand, a solution so strong as to repel organisms in pure water, will, in dilute malic acid, attract them. The spermatozoon of the fern, to use the classic example, when in a weak solution of malic acid are attracted by a solution so strong as to repel the spermatozoa when the latter are in pure water.

Negative chemotropism may therefore, under changed conditions, become positive. This fact is of cardinal importance in Hertwig's conception of immunity.

The white cells of the blood are apparently very susceptible to chemotropic influences. The metabolic products of pathogenic bacteria — whether "ptomaines," "toxines," or something else — exert in general, a positive effect upon the leucocytes and so draw them towards the source of the stimulus, that is to the "inflammatory centre."

Hertwig points out that the numerous chemotropic possibilities group themselves under two heads. In the first place, the metabolic bacterial products may be present in the blood and in the diseased tissues in

¹ Über die physiologische Grundlage der Tuberkulinwirkung: eine Theorie der Wirkungsweise bacillärer Stoffwechselprodukte, Jena, 1891.

almost or quite equal proportions. In this contingency there will be no effective chemotropic stimulus, and the leucocytes will consequently not be drawn towards the affected locality.

In the second place, the substances accumulated in the blood and diseased tissues are of different degrees of concentration in the two places, and this difference causes a chemotropic movement of the leucocytes. Here there are obviously two possibilities, either the higher concentration exists in the blood or in the diseased tissues. In the latter case the leucocytes are drawn into the affected locality; this is perhaps the most ordinary and well-known condition — as in suppuration. In the former case the leucocytes, which in other conditions might have gathered in the diseased area, are retained in the blood-vessels.

In Hertwig's opinion the action of Koch's tuberculin can be best explained by reference to some such chemotropic phenomena. Suppose that the metabolic products of the tubercle bacilli are in so high a degree of concentration in the tissues as to exert a repellent, or negatively chemotropic, effect upon the leucocytes, which, in consequence, shun the affected area. On the injection of tuberculin into the blood the leucocytes, after the analogy of the spermatozoa and malic acid, become attracted by the bacterial substances in the tissues which were previously so relatively concentrated as to repel. In this way Hertwig thinks to explain the reactions following the introduction of tuberculin into the blood. On this assumption also he believes it possible to explain many of the perplexing and disastrous consequences of injections of too large quantities of tuberculin. He concludes that Koch's application of tuberculin injection "rests upon a thoroughly sound physiological foundation."

Hertwig's further treatment of the subject ventures upon the much controverted ground of the phagocytetheory and its implication. He considers that Metchnikoff's view is essentially correct and refers the artificial production of immunity to the greater sensitiveness which the leucocytes have acquired toward the bacterial products, and consequently toward the bacteria themselves. The arguments presented in support of this view are perhaps more ingenious and suggestive than convincing.

MEDICAL NOTES.

RESTRICTION OF IMMIGRATION. — Secretary Foster has suggested to Congress that the head tax of fifty cents on each immigrant be abolished and that a tax of one dollar, to be paid by the importing company, be substituted; also that each company file a bond of not less than \$50,000 for the return of immigrants found within two years after landing to have been brought in contrary to the laws of the United States. A system of preliminary inspection before embarking is also proposed, to be under the charge of a body of commissioners and inspectors responsible to the United States Consuls.

THE RIOTS IN BERLIN. — As a result of the riots in Berlin last week, there were twenty-five admissions to the hospital, the principal injuries being broken arms and legs and sabre cuts.

INFLUENZA IN EUROPE. — During the week ending February 13th, the epidemic of influenza in London had sensibly diminished. The death-rate was thirty per thousand. In most of the Continental cities, the disease appeared also to be decreasing. In Vienna an epidemic of intestinal catarrh followed the previous influenza epidemic. Whether there is any connection between the two has not been definitely settled.

SIR MORELL MACKENZIE'S FEES. — According to the *Medical Press*, it is stated that the sum, which the late Sir Morell Mackenzie was paid for his attendance on the late German Emperor was £12,000. After this a hundred guineas for removing an elongated uvula seems a comparatively moderate fee for such an operation, but this was what the distinguished specialist received a few months ago from an eminent lawyer who was under his care for this affection.

A WARNING FROM VIRCHOW. — The correspondent of the *Lancet* says that on February 9th, Professor Virchow addressed the following to one or more of the Berlin papers: "Cincinnati papers publish lengthy advertisements, according to which the 'great German physician,' Dr. Karl Virchow Schick, has arrived there from Berlin and opened his consultations. It is alleged that he has made important discoveries in the germinal treatment of chronic diseases, and that his prescription is used by 806 doctors in Europe. Permit me to remark that, according to the official lists, there is not and never has been a physician of this name in Berlin or in Prussia, and that such a one from the other States of the German Empire is also not known. It is hoped that this notice will suffice to induce the American papers to oppose the tactics of the gentleman in question."

INSTRUCTION FOR GERMAN ARMY SURGEONS. — In order that the Prussian medical officers shall have an acquaintance with the new discoveries in the department of public medicine, arrangements have been made for their attendance on a course of lectures to be held in all the Prussian Universities. These courses will extend over three weeks of each year at the end of the regular session, and it will be incumbent on each surgeon to attend one such course.

TUBERCULOSIS AND EARTHWORMS. — MM. Lortet and Despeignes have published the results of some experiments showing the connection between the common earthworm and the tubercle bacillus. They find that the bacillus may remain for several months in the worm without changing its virulence.

BOSTON AND NEW ENGLAND.

MORTALITY OF BOSTON. — The number of deaths reported during the past week was 197, making the death-rate 22.3. Four deaths were due to influenza, 29 to consumption, 34 to pneumonia, 15 to heart dis-

ease and 11 to bronchitis. The number of persons who died over sixty years of age was 42.

BOSTON BATH HOUSE CO.—A company is soon to be incorporated with the above title to establish baths for the poor of Boston, following the steps of the chief European cities and the recently established People's Baths in New York. There is already a small establishment of this kind in Boston where, during the first year, three thousand men, women and children made use of it. It is hoped that after the baths are established they will be self-supporting. About \$40,000 are needed for the establishment of the institution.

A BEQUEST TO INSTITUTIONS.—By the will of the late Caroline P. Adams, of Newton, the following are among the public bequests: Children's Hospital, \$2,500; Adams' Nervine Asylum, \$10,000.

DEFILEMENT OF THE BEACHES.—The Committee on Public Health of the Massachusetts Legislature has recently considered a petition of the town of Swampscott for legislation to protect that town and other towns from injury and danger to the public health occasioned by the floating back of the garbage and filth of the City of Boston on to their beaches and shores.

NEW YORK.

TYPHUS FEVER.—During the last week several deaths have occurred among the typhus fever patients on North Brothers' Island, and some twenty-five cases have been pronounced well. A number of new cases have occurred among the Russian Hebrews of the *Massilia*, and notwithstanding the energetic efforts of the sanitary authorities to prevent the spread of the disease, a few cases have developed among people, not of this class, who frequent the cheap lodging-houses. In two or three instances the nature of the trouble was not discovered until after the patients had been removed to Bellevue Hospital. All suspicious cases at that institution are now isolated and carefully watched, and as soon as it becomes evident that the disease is typhus the patient is transferred to the hospital for contagious diseases at North Brothers' Island.

CITY CARE OF THE INSANE.—The advisory committee appointed by the Mayor to make a thorough investigation and report as to the best means of taking care of New York City's pauper insane, after inspecting the institutions on Ward's and Blackwell's Islands, where they found the conditions so unfavorable on account of the inadequacy of the buildings and the overcrowding of the inmates, made a visit to the City's Farm for the Insane at Central Islip, Long Island, where there are now 250 acres under cultivation by the patients, and discovered a most marked and favorable contrast in the state of affairs. More recently they visited the Binghamton and Willard State Hospitals for the Insane, and their report, which is now being prepared, will soon be presented.

STATE CHARITIES.—The Twenty-fifth Annual Report of the State Board of Charities was recently

transmitted to the Legislature, and shows the value of the property held by the charitable, correctional and reformatory institutions of the State on October 1, 1891, to be something over \$72,000,000 as against about \$64,500,000 at the same date the preceding year. The number of inmates in these various institutions was 747,773, an increase of 3,878 during the year, and of these 16,647 were insane. Total increase of insane in the last eleven years has been 7,110, or nearly seventy-five per cent., while the increase in the general population of the State has been only about nineteen per cent.

CENTENARIANS.—Two centenarians have died in the city during the past week. The first was Mrs. Mary Clemints, who was born in Ireland and when she came to this country twenty-eight years ago she brought with her her baptismal record, which shows her to have been one hundred and three years, eight months, and fifteen days old at the time of her death. She had nine children and her descendants are now very numerous. She always enjoyed perfect health, and of late years had lived with a son, now eighty-four years old. She kept house for him, and on the day that she died, got up at five o'clock as usual to attend to her morning duties. The other centenarian was an Italian whose age was reported to the Bureau of Vital Statistics as one hundred and five years. For two years past he had been an imbecile. The oldest woman of the Tonawanda Indians died in February, on the reservation near Buffalo, at the age of one hundred and two. She was the widow of the Warrior Black Squirrel who distinguished himself on the Niagara frontier in the War of 1812.

Miscellany.

BULLET WOUNDS FROM THE MANNLICHER RIFLE.

An Italian officer who had the opportunity of studying gun-shot wounds made with the Mannlicher rifle during the late war in Chili describes these wounds as different from those produced by the older weapons.¹ They either kill on the spot or produce a wound which is generally not very serious. Even at long range bones are pierced without leaving behind pieces of steel or lead, and also without producing splintering of the bone to any extent. The balls which were removed from wounds had entirely preserved their form, not being either flattened or broken. The author promises soon an extended report on the subject which will be of great interest to military surgeons. These peculiarities of modern rifle bullets have been noticed already by Professor Bartleben in Berlin, who said that in case of war, wounds made by the present German infantry would be characterized by the straightness of the course of the bullet and the lack of injury to the neighboring soft parts. The bullet is of small calibre, made of lead coated with steel, and is sent with great velocity.

¹ Wiener klin. Woeh., February 11.

IN MEMORIAM. DR. HENRY I. BOWDITCH.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

The Boston Society for Medical Improvement honors itself in honoring the memory of Dr. Henry Ingersoll Bowditch, and in placing upon the records of the Society its appreciation of his services to medicine and its admiration of his character.

Dr. Bowditch was for fifty-seven years a member of our Society, and was, until his health failed, most constant in his attendance at our meetings. His ardent, eager zest for any knowledge that might help his patients; his fervid advocacy of every movement to benefit medical science or raise the standard of our profession; his generous recognition of all earnest, true work; his respect for every honest opinion; his frank criticism of what he held to be untenable; his zealous defence of the right; — his strenuous support of every good act or thought, — are familiar to us all. His quick intuition and ready sympathy, his innate sense of justice and intense love of truth, the genuineness of his purpose, the unselfishness of his life, the sincerity of his friendship, will always be held by us in grateful and loving remembrance.

His faithfulness to his trust marked him as the physician. His heroism, his public service, the labors and the distinctions of his loved profession brought out in bolder relief the simplicity and modesty of the man.

To Dr. Bowditch's family the Society respectfully offers its sincere sympathy.

CHARLES F. FOLSOM,
GEORGE B. SHATTUCK,
EDWARD H. BRADFORD.

METHYLENE-BLUE IN CYSTITIS.

AT a recent meeting of the New York County Medical Association, Dr. Joseph N. Henry presented two specimens of bright blue urine, which, he said, were from patients suffering from chronic cystitis whom he had been treating with an aniline dye. He had adopted this plan in consequence of reports which he had seen in German journals, and it was his practice to give one grain of methylene-blue three times a day, after meals. One of the patients, who had been suffering for over two years, had locomotor ataxia and prostatitis, and gave a syphilitic history. There had been twenty per cent. of mucus in the urine; but in three weeks this had been reduced to one or one and one-half per cent. The other case was non-specific, and the patient had just been discharged cured.

METHYLENE-BLUE IN MALARIA.

FOLLOWING the suggestion of Guttmann and Ehrlich, Thayer¹ reports five cases of malaria treated at the Johns Hopkins Hospital with methylene-blue. The usual dose was one and a half grains five times a day.

In all the cases the urine was carefully examined, and no albumen was at any time found. In all of the cases where methylene-blue alone was given, its administration was followed within the first three days by slight stranguary, which, however, was immediately relieved by nutmeg, and in the cases where nutmeg was given in the beginning there were no unpleasant results. The urine in all the cases was of a deep blue color; the faces, though untinged when passed, be-

came blue on exposure to air. The sweat and saliva, however, did not appear to be colored.

All of the cases, with the exception of one, were of the more chronic and severe types of malarial fever, those in which the hyaline intracellular bodies and the crescents have been found. It is a well-known fact that in these cases quinine is often very slow in its action, and that with the combined administration of quinine and arsenic, organisms may be found in the blood for weeks and months. The one case of common tertian ague yielded almost immediately to the methylene-blue, the organisms disappearing on the third day. In another case the organisms had not entirely disappeared in twenty-three days. This was a severe chronic case. In a third case, which appears to have been one of the more severe varieties, no organism was seen after the ninth or tenth day. In none of the cases was there any chill later than twenty-four hours after the beginning of the administration of methylene-blue. The doses of methylene-blue were not large, and it is hard to know with what dose of quinine to compare them. The author concludes that methylene-blue certainly has, as Ehrlich and Guttmann claim, a distinct anti-malarial action, a fact which is certainly of great interest, and it would be well if more observers in this country were to carefully follow up this question.

THE MONGOLIAN EYE.

KOMOTO¹ has studied in detail the differences between the characteristic eye of the Mongolian nations, and of the Caucasian race. The difference between the two is caused neither by the size of the eye-ball, nor the color of the iris, which is the same in both, but in the shape of the eye-lids. The epicantus, a fold of the skin covering the inner canthus, is rare in adult white persons, but exists physiologically among the Japanese, so that it is sometimes called the Mongolian fold. In the majority of cases this fold runs obliquely inwards and downwards from the upper lid, so that the inner canthus is not round as in white people, but is sharp. When the fold is large it spreads to the inner part of the lower lid, in which case the upper lid does not cross the cornea horizontally, but obliquely, giving the peculiar expression to the eye often met with in Japanese.

Another peculiarity of the upper lid in Mongolians is the lack of development of the orbital furrow, the groove below the eye-brows. The skin covering the upper lid is very loose, so that when the cartilage is raised the skin is thrown into a transverse fold. When this fold is well developed it droops slightly over the margin of the lid. This interferes with the eye-lashes, directing them downwards instead of forwards.

In Japanese the cilia are short and straight. On the lower lid they are sometimes so badly developed and so few in number that they appear at first to be absent. When well developed they are sometimes bent inwards by the peculiar formation of the upper lid, and may seriously irritate the cornea. Except for this there is no great difference in the lower lid of Mongolians and Europeans. The margin is generally more curved in white people, so that there is often a portion of the sclerotic exposed between the lid and the cornea, a peculiarity, the author remarks, which makes "their eyes looking apparently upwards gener-

¹ Johns Hopkins Hospital Bulletin, vol. iii, no. 19.

¹ Sei-I-Kwai Medical Journal, December 26, 1891.

ally." As the skin of the lid is less firmly connected to the subjacent tissues in the Japanese, entropion is more common, but ectropion less common among them than among Europeans.

THERAPEUTIC NOTES.

TO DETECT SUGAR IN URINE. — Flint¹ describes a simple apparatus for detecting the presence of sugar in the urine, when the results of Fehling's test are uncertain. A small straight bottle or a small test-tube is fitted with a cork, through which is passed a small tube that reaches nearly to the bottom. The glass tube is bent so that the apparatus will hang over an ordinary test-tube or other convenient vessel. The bottle is completely filled with urine, with which a piece of Fleischmann's yeast, about the size of a pea, has been thoroughly mixed. In putting in the cork it is necessary to be careful to exclude every bubble of air. If the apparatus be kept for a half-hour at a temperature of from 80° to 90° F., a bubble of gas will appear if sugar be present in the smallest quantity. The apparatus may be placed in the sun or near a heater, but the temperature should not be higher than 100°.

STRONTIUM FOR TAPE-WORM. — At a recent meeting of the Academie de Medecine M. Laborde said that he found that the salts of strontium had a very destructive action on the eggs or germs of the tenia. He made several experiments on dogs, and he employed the salts in man, obtaining very satisfactory results.

FORMULA FOR WINE OF COCA:²

R. Coca-leaves	3 lb.
Cognac	3 lbs.
Sherry wine	10 lbs.
Hungarian wine	3 v. l. M.

Macerate for several days and add seven grains of citric acid. Allow this mixture to stand for several days, and then filter.

Correspondence.

INEXPERT EXAMINATIONS FOR ARSENIC.

BOSTON, February 28, 1892.

MR. EDITOR: — I have been much annoyed, and my patients have been needlessly alarmed, in three separate households, by serious errors in the results of examination for arsenic; and in two of these households the wall-papers declared dangerous had been sold as harmless upon the guarantee of accomplished chemists. In a fourth case coming to my knowledge, harmless wall-paper, bought with a similar guarantee, was needlessly removed upon being declared dangerous by an inexpert analysis. One of my patients was very much frightened upon being told to consult a physician at once, as there were said to be albumen and casts in the urine, when I ascertained that there was no evidence of renal disease; and the urine was declared free from arsenic although a subsequent examination by a competent chemist revealed too large a quantity of arsenic to have come from wall-paper alone.

I write this to indicate the importance of having all chemical analyses for arsenic and all clinical examinations of urine made by persons thoroughly fitted for their work.

Respectfully yours, CHARLES F. FOLSOM, M.D.

¹ Medical News, January 9th.² Pharmaceutische Post, No. 27, 1891.

METEOROLOGICAL RECORD.

For the week ending February 20, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 2,450: under five years 876; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoea, diphtheria, whooping-cough, fevers, &c.) 224, according to diseases 492; consumption 230; diphtheria and erysipelas 225; typhoid fever 21; measles 15; whooping-cough 14; cerebro-spinal meningitis 8; small-pox 2; typhus fever 2; malarial fever 1.

From erysipelas New York 10, Brooklyn 3, Nashville 2, Boston 1, Cleveland, Pittsburgh, Washington, Fall River and Chelsea 1 each. From typhoid fever Pittsburgh 8, Brooklyn 4, New York, Cincinnati and Washington 2 each, Milwaukee, Lowell and Lynn 1 each. From measles New York 13, Brooklyn and Worcester 1 each. From whooping-cough New York 6, Boston and Pittsburgh 2 each, Brooklyn, Milwaukee and Fall River 1 each.

From cerebro-spinal meningitis Brooklyn, Cincinnati and Washington 2 each, Boston and Lynn 1 each. From small-pox New York 2. From typhus fever New York 2. From malarial fever Brooklyn 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,185,736, for the week ending February 6th, the death-rate was 26.2. Deaths reported 5,106: acute diseases of the respiratory organs (London) 761, influenza (London) 314, whooping-cough 240, measles 72, diarrhoea 38, diphtheria 36, scarlet fever 31, fever 30.

The death-rates ranged from 13.8 in Bradford to 39.6 in Northampton; 21.1 in Cardiff 25.3, Hull 22.7, Leeds 17.1, Liverpool 16.2, Liverpool 27.1, London 30.6, Manchester 24.2, Newcastle-on-Tyne 26.6, Nottingham 26.4, Portsmouth 30.6, Sheffield 20.9, Sunderland 20.8.

In the thirty-three greater towns of England and Wales with an estimated population of 10,185,736, for the week ending February 13th, the death-rate was 23.1. Deaths reported 4,514: acute diseases of the respiratory organs (London) 560, whooping-cough 192, measles 66, diarrhoea 46, scarlet fever 39, diphtheria 34, fever 8, small-pox (Oxford) 1.

The death-rates ranged from 16.6 in Bradford to 32.0 in Nottingham; Birmingham 20.9, Brighton 24.6, Huddersfield 17.3, Leeds 17.9, Leicester 22.9, Liverpool 24.1, London 24.6, Manchester 24.9, Newcastle-on-Tyne 27.1, Sheffield 19.8, Sunderland 20.8, Wolverhampton 23.1.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING FEBRUARY 27, 1892.

V. C. B. MEANS, passed assistant surgeon, detached from Naval Hospital, New York, and to Navy Yard, New York.

GEORGE A. LUNG, assistant surgeon, detached from Navy Yard, New York, and to Naval Hospital, New York.

E. H. MAHESSELLER, passed assistant surgeon, detached from Marine Rendezvous, Baltimore, and wait orders.

F. J. B. CORDEIRO, passed assistant surgeon, detached from Marine Rendezvous, Boston, and to the U. S. "Adams."

EXAMINATIONS FOR GRADE OF ASSISTANT SURGEON, UNITED STATES MARINE-HOSPITAL SERVICE.

WASHINGTON, D. C., February 23, 1892.

A board of officers will be convened in Washington, May 2, 1892, for the purpose of examining applicants for admission to the grade of Assistant Surgeon in the United States Marine-Hospital Service.

Candidates must be between twenty-one and thirty years of age, graduates of a respectable medical college, and must furnish testimonials from responsible persons as to character.

The following is the usual order of the examinations: (1) Physical, (2) written, (3) oral, (4) clinical.

In addition to the physical examination, candidates are required to certify that they believe themselves free from any ailment which would disqualify for service in any climate.

The examinations are conducted in writing, and begin with a short autobiography by the candidate. The remainder of the written exercise consists in examination on the various branches of medicine, surgery and hygiene.

The oral examination includes subjects of preliminary education, history, literature and the natural sciences.

The clinical examination is conducted at a hospital, and when practicable, candidates are required to perform surgical operations on the cadaver.

Successful candidates will be numbered according to their attainments on examination and will be commissioned in the same order, as vacancies occur.

Upon appointment the young officers are, as a rule, first assigned to duty at one of the large marine-hospitals, as at Boston, New York, New Orleans, Chicago or San Francisco.

After four years' service, assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon.

Promotion to the grade of surgeon is made according to seniority and after due examination as vacancies occur in that grade. Assistant surgeons receive sixteen hundred dollars, passed assistant surgeons eighteen hundred dollars, and surgeons twenty-five hundred dollars a year. When quarters are not provided, commutation at the rate of thirty, forty, or fifty dollars a month, according to grade, is allowed.

All grades above that of assistant surgeon receive longevity pay, ten per centum in addition to the regular salary for every five years' service up to forty per centum after twenty years' service.

The tenure of office is permanent. Officers travelling under orders are allowed actual expenses. For further information or for invitation to appear before the Board of Examiners, address:

WALTER WYMAN, Supervising Surgeon-General, M. H. S.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.—A regular meeting will be held at 19 Boylston Place, on Monday, March 7, 1892, at 8 o'clock, P. M.

Readers: Dr. J. B. Ayer, "The Third Year of the Influenza Epidemic"; Dr. S. H. Ayer, "A Case of Empyema, with Recurrence after Apparent Recovery"; Dr. F. L. Jack, "Operative Treatment for the Relief of Chronic Suppurative Affections of the Middle Ear. Report of Three Cases." Discussion by Drs. J. O. Green, C. J. Blake and others.

Report of Treasurer.

Report of Committee on Admissions.

Appointment of committee to nominate officers for the ensuing year.

JOHN C. MUNRO, M.D., Secretary.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT, SECTION FOR OBSTETRICS AND GYNECOLOGY.—A regular meeting will be held at 19 Boylston Place, on Wednesday, March 9, 1892, at 8 o'clock, P. M.

Dr. George W. Van Pelt will report a Case of Pyro-salpinx; Dr. W. L. Burrage will read on "The Electrical Treatment of Pelvic Inflammations." Dr. E. L. Burt will present a paper on "Inflammations of the Pelvic Organs."

GEORGE HAVEN, M.D., Secretary.

92 Pinckney Street.

ASSOCIATION OF AMERICAN PHYSICIANS. PRELIMINARY ANNOUNCEMENT.—The next annual meeting will be held on Tuesday, Wednesday and the morning of Thursday, May 24, 25 and 26, 1892, in the Medical Museum and Library, Washington, D. C.

The subject selected for discussion is Dysentery. Dr. William T. Councilman, as Referee, will consider the Etiology and Pathology, and Dr. A. Brayton Ball, as Co-referee, the Symptomatology, Complications and Treatment.

The following members will present papers: Henry M. Lyman, The President's Address; Charles Carey, The Production of Tubular Breathing in Consolidation and Other Conditions of the Lungs; Samuel G. Chew (Title to be announced later); William H. Parker, A Comparative Study of the Bactericidal Action of the Air; Francis T. Miles, The Treatment of Follicular Tonsillitis; George M. Garlands, The Morbid Anatomy of Leprosy; Hobart A. Hare, A Collective Investigation in regard to the Value of Quinine in Malaria Haematuria or Malarial Haemoglobinuria; A. Jacobi (Title to be announced later); W. W. Johnston, Treatment of Acute Dysentery by Antiseptic Colon and Rectal Irrigation; Thomas S. Latimer, Alcoholism; Morris J. Lewis, A Study of the Seasonal Relations of Chorea and Rheumatism for a period of fifteen years; Morris Longstreth (Title to be announced later); Francis T. Miles, A Case presenting the Symptoms of Laryngeal Paralysis with Recovery; William Pepper, Report of Cases of Glaucoma with results of Bacteriological Examination; T. Mitchell Prudden (Title to be announced later); George M. Sternberg, Practical Results of Bacteriological Researches; Charles G. Stockton, Misconceptions and Misnomers Revealed by Modern Gastric Research; William H. Thompson, The Significance of Intermission in Functional Nervous Diseases; Victor C. Vaughan, Certain Toxicogenic Germs found in Drinking-water; B. F. Westbrook, Studies in Hypnotism; James C. Wilson, Pulsating Pleural Effusions; George Wilkins, The Cold Water Treatment of Typhoid Fever.

HENRY HUN, Secretary, 35 Elk Street, Albany, N. Y.

RECENT DEATHS.

ALEXANDER LUMNITZER, M.D., Professor of Surgery in the University of Buda Pesth, died January 30th, aged seventy. He was knighted in 1866, became professor extraordinary in 1872, president of the Hungarian National Board of Health in 1878 and a member of the upper house of parliament in 1885. He was the author of several works on surgical and sanitary subjects.

BOOKS AND PAMPHLETS RECEIVED.

Transactions of the American Ophthalmological Society, Twenty-seventh Annual Meeting. 1891.

Manual of Operative Surgery. By Frederick Treves, F.R.C.S., Surgeon to and Lecturer on Anatomy at the London Hospital etc. Volumes I and II. Philadelphia: Lea Brothers & Co. 1892.

First Lines in Midwifery. A Guide to Attendance in Normal Labor for Medical Students and Midwives. By G. Ernst Hermann, M.B., F.R.C.P. Obstetric Physician to the London Hospital, etc. Philadelphia: Lea Brothers & Co.

The Human Figure: Its Beauty and Defects. By Ernst Brücke, Professor of Physiology, University of Vienna. With a Preface by William Anderson. Authorized translation, revised by the author. With 22 illustrations by Hermann Parr. London: H. Gravel & Co. New York: B. Westermann & Co. 1891.

TWO FATAL CASES OF CEREBRAL DISEASE (ONE OF CONFUSIONAL INSANITY THE OTHER OF DOUBTFUL NATURE) FOLLOW- ING GRIPPE.

BY MORTON PRINCE, M.D.,

Physician for Nervous Diseases, Boston City Hospital.

THE following two cases of cerebral disease caused by the grippe are of interest because they illustrate the profound effect of the poison of the disease upon the central nervous system. One was a case of confusional insanity, the other was of doubtful nature. As a rule, confusional insanity ends favorably, but this case illustrates the possibility of fatal termination. Although the subject had suffered from chronic bronchitis for many years, his physical condition otherwise was good up to the time of his infection with the grippe, and therefore I think his previous physical condition contributed little towards the fatal result, although from reading, merely, an account of the case, it might seem otherwise.

Attention has often been called, and of late particularly by Althaus and Mills,¹ to the affinity of the poison of influenza for the nervous system. Although Althaus, it seems to me, goes too far in relegating the inflammation of the mucous membranes to a place of secondary importance and in considering the disease as an essentially nervous fever, still it does not seem to me that the action of the poison upon the nervous system in cases of the bronchitic type is regarded in practice as having the importance that should be attached to it. Symptoms and physical conditions are ascribed to general weakness and exhaustion, which are in reality due to what might be better called a paresis of the nerve centres. In other words, the so-called exhaustion of grippe is not an exhaustion in the true sense of the word, but is really the expression of a true neurosis which is due to the toxic or paralytic effect of the poison on the nerve centres, just as the paralysis of diphtheria is toxic and not exhaustive. When both pulmonary and abdominal symptoms are absent, the neurosis stands out prominently in the foreground and is plainly recognized; but when these symptoms are present their more strikingly objective character overshadows the neurosis which in consequence is apt to be overlooked or underestimated.² A prolonged convalescence with its train of nervous symptoms and even death then come not unfrequently as a surprise. The fatal result, so often unexpected, is fully as much, in my judgment, due to this neurosis as to the bronchitis. The latter, if occurring by itself, would not be sufficient to cause death.

The acceptance of these views must affect the after-treatment and the prognosis.

CASE I. The patient, a man sixty-six years of age, and a sufferer for the past thirty-five years with chronic bronchitis, was taken December 19th last with symptoms of an acute exacerbation. As the patient had had several such attacks in the past it was impossible, at first, to say whether or not the acute bronchitis was due to the grippe or was simply an increase of the old

trouble. There were no symptoms, in the beginning, to throw light on the etiology. Later, it became evident that his symptoms were caused by grippe. The fever was moderate and lasted about a week or ten days; the highest point reached was 102.5°, although it should be said the temperature might have been modified by the phenacetine, which was given in moderate doses.

The bronchitis was very severe. Very large quantities of muco-purulent sputa were raised in the twenty-four hours; and the patient suffered from intense dyspnoea, which prevented his lying down in bed. It should be said that repeated examinations of his lungs during the past year had shown the existence of marked emphysema, bronchiectasies, and abundant coarse and fine moist râles throughout the lungs. The apices were particularly affected, and the right one in particular gave physical signs of phthisis. Examination of the sputa had failed, however, to show the existence of bacilli, and while the objective signs simulated those of phthisis, the symptoms were all those of bronchitis. With the exception of great dyspnoea on exertion, and cough, particularly in the mornings, when the patient raised considerable quantities of muco-purulent expectoration, he had enjoyed fair health. His physical appearance had always been good and was in no way suggestive of phthisis. Dr. F. C. Shattuck, who saw the case with me in consultation, confirmed this view of the lungs, excepting that he considered there was fibroid condition also present.

After the first week of the attack of grippe, the bronchitis gradually and steadily improved until, at the end of his illness, it had subsided to its previous condition. The cough was moderate, troubling him but little, and the expectoration was comparatively slight. The sputa were again examined for bacilli, with negative results. The interest of the case centres in the nervous symptoms.

During the first week the patient suffered from marked depression, so marked, indeed, as to almost amount to melancholia. However, as it was known that he always became very much depressed when ill, it did not excite very much attention. During the next week, a stuporous condition developed. The patient frequently fell, if not into a sleep, at least into a somnolent condition while talking, and it was with difficulty that his attention could be held for more than a few minutes at a time. During the third week his mental condition changed again; the stupor disappeared; the melancholia gave place to a condition approaching exaltation. He appeared to be in abnormally good spirits, and to have entirely lost all apprehension on account of his condition. At the same time a peculiar kind of delirium now developed resembling in many respects that of delirium tremens. At first, it was limited to bad dreams; with these the patient was tormented, particularly at night, but also if he fell asleep in the daytime. By degrees the dreams persisted after he was waked up, and he seemed to find it difficult to throw them off. Then they persisted as false ideas and experiences during the waking state, and he became unable to distinguish between his dream life and his real life. By degrees hallucinations and illusions developed during the day; he saw people in his room, and objects outside in the street, which did not exist, and a chain of delirious ideas took complete possession of his mind. He found difficulty at times in expressing himself intelligently. Wrong words were

¹ An excellent editorial in a late number of this Journal has emphasized this subject.

² In the Journal of February 4th last, two cases are reported of the supposed effect of snuff-nail in producing a relapse (↑) with nervous symptoms. It seems to me these are plainly cases of neurosis due to the grippe, and illustrate the point made in the text.

interpolated in his sentences, and the words themselves slovenly pronounced. The mental confusion was marked in regard to his surroundings. He imagined himself in various and impossible situations. He recognized, however, everybody about him and the facts of his illness. In fact, his mental condition was, as has been said, very similar to that of delirium tremens. The marked difference was, that while he was, and had been, during the whole attack tormented by bad dreams, and he required hypnotics every night, sleep was easily induced by moderate doses. Hyoscin, in doses of one one-hundred-and-fiftieth of a grain, gave quiet sleep during the greater part of the night.

Examination of the urine showed the kidneys to be free from disease. Eight days before he died Dr. Jelly saw him with me in consultation. At that time there did not seem any reason for apprehending a fatal issue, but during the next few days his mental condition rapidly grew worse.

An interesting point in the case, and one which, to my mind, bears upon the pathology of such cases, was the fact that while his mental condition was progressively growing worse, his physical condition was progressively improving. The bronchitis was subsiding; his dyspnea was growing less; his appetite improved so that he took large quantities of food, in fact, more than he had been in the habit of taking previous to his illness, and his strength increased to the extent that he was able to sit up in a chair for seven or eight hours a day. His pulse remained strong and full up to the last few days of his illness, and ranged in the neighborhood of 90. When the hallucinations developed he was put back to bed, and he was treated with large doses of cardiac and cerebral stimulants. His mental condition grew steadily worse, and he died January 25th, thirty-nine days after being taken sick. It was only during the last two or three days of his illness that he failed physically, and on the last day he sank rapidly.

CASE II. This case I saw in consultation with Dr. John G. Blake, who has kindly given me his notes in the case.

The patient, a man, forty years old, had always been more or less affected with chronic bronchitis of moderate intensity. He was also of moderately alcoholic habits, depending upon the use of stimulants in rather excessive quantities, although never, perhaps, intoxicated. He was attacked with grippé in January last, and attended by Dr. Blake. He was ill two weeks, the principal symptoms being those of bronchitis. At the end of two weeks the symptoms subsided, and he recovered strength sufficiently to be up and about the house and even to walk a short distance to Dr. Blake's office; he still, however, continued weak.

At the end of about five days severe neuralgic pains developed in the scalp; these appear to have been intense, and the scalp became very sensitive to the touch. For two days, however, he appeared to be otherwise well, and talked rationally. He then became troubled at night with delirium, or dreams, which gradually persisted into the day. There had been no vomiting or convulsions. A delirious condition with hallucinations rapidly developed; and when seen by me, in consultation, on the morning of the fourth day, his condition was as follows:

He was in bed, but his muscular condition seemed to be strong; pulse, strong and full; not rapid, nor abnormally slow. He was in a stuporous condition,

although it was evident that his mind was occupied with hallucinations. When disturbed, he played with the pillow and moved about in bed. There was no paralysis of any kind: he protruded his tongue, and answered questions. His condition gave the impression of a meningitis. Insomnia had been marked. The temperature was not taken with the thermometer, but to the touch it did not appear to be raised. Dr. Blake says there never had been any suspicion of fever. Arrangement was made to transfer the patient to the hospital; but later some objection having been made, he did not go. "That evening his delirium," Dr. Blake says, "became even more marked and was of the muttering variety." He talked indistinctly and incoherently. He could not be roused to answer intelligently. The pulse continued full and strong. There was retention of urine and he required to be catheterized. The report of the night-watch was that he continued about the same until about 4 A. M. He then became more restless and began to fail. He died about 7 A. M. Thus it will be seen that the chief and almost only symptom was delirium preceded by neuralgic pain in the head. An autopsy was not allowed.

The diagnosis lay between meningitis and some form of toxic cerebral disease due to the poison of grippé. It was expected that after the patient's transfer to the hospital a more satisfactory study could be made, but his unexpected death prevented this.

REMARKS.

The first of the above cases was plainly one of confusional insanity, a name given by Wood, of Philadelphia, to designate the form of mental disturbance often met with following acute febrile diseases such as acute rheumatism, typhoid fever, grippé and even surgical operations. This form of brain disease has, of late, attracted much attention, both here and in Germany, and several monographs have appeared upon the subject. A number of cases are to be found reported in the medical journals, Osler, for instance, has reported five cases, of which four followed typhoid. Wood, who has most exhaustively discussed it, considers that pathologically it is due to the exhaustion of the nerve centres and not to the toxic effect of the specific poison of such diseases as above mentioned. He believes that its pathology is always the same, whether following a surgical operation, the puerperal condition or acute infectious diseases. These conditions induce a state of exhaustion which in turn brings about one of malnutrition of the brain. It seems to me that this view may be fairly questioned. It is undoubtedly true that mental disturbance may follow physical exhaustion, pure and simple, as, for example, when produced by starvation and exposure after shipwreck. Still, it seems to me that clinical evidence also points to the direct toxic action of the poison itself as the true cause in many, if not all, cases of acute infectious diseases. In the case just quoted, for example, it will be noticed that the first mental disturbance, namely, the melancholia developed during the few days of the disease before exhaustion, could properly be said to have occurred: and more than this, instead of the physical condition of the patient deteriorating as the mental disturbance progressively increased, on the contrary, the physical strength steadily improved while the stupor, hallucinations and other mental symptoms steadily grew worse. In fact, while the appetite, strength and the bronchitis were steadily improving, he was

mentally failing. Nor was there at any time in the course of the disease evidence of weakened function of the vital organs beyond a temporary gastric disturbance shown by an exceedingly furred tongue, due partly to over-feeding.

Taking these facts into consideration, and taking also into consideration the fact that delirium in grippa may be prominent on the first day without fever, bronchitis or other local symptoms (one example of which I have seen), and that it may also occur early in gonorrhonal rheumatism before any exhaustion has developed (an example of which I have also seen) I am disposed to consider the psychical disturbance as dependent on the direct toxic effect of the poison on the cerebral tissue. An analogous condition, and one beyond question, is the mental disturbance observed in Bright's disease. This distinction is of some practical importance because if the weakness, or rather, as I believe it should be regarded, the paresis, the mental and other symptoms occurring during and following grippa are simply to be regarded as evidences of exhaustion, the treatment is simple and the prognosis will have a more favorable outlook; but if these conditions are in reality toxic in their character, it is evident that the treatment of this nervous condition should be much more watchful and serious and the prognosis more guarded. I am certain that the surprise often expressed at the unexpected fatal termination of many cases of grippa is due to the profound toxic effect of the poison on the nervous system not having been recognized. It is not a mere weakness that we have to do with but a real paralysis of the nervous system. I am inclined to regard the great fatality in aged people as due only in part to the local lung complications, pure and simple, and at least in an equal degree to this nervous poisoning often resulting in paralysis of the heart. It is true that confusional insanity in the great majority of cases has a favorable termination, but the above case illustrates its dangers. I am sorry that the sudden termination of the second case, above described, prevented more careful study of the conditions it presented. I think the diagnosis must remain in doubt, but that it will lay between meningitis and toxic neurosis.

CASES OF ATROPINE AND OPIUM POISONING IN EARLY LIFE.¹

BY T. M. BOTCH, M.D.,
Visiting Physician to the Boston City Hospital and the Children's
Hospital.

THE following cases are reported more for their clinical interest than for making any precise deduction as to the amount of atropia or morphia which may produce death or be recovered from at any especial age in infancy or childhood. In fact, any such deductions must be based on an extremely large number of cases to be of any definite value, for infants and children appear at the same age to vary considerably as to the amount of these drugs which they can absorb and eliminate without physiological or toxic symptoms. A dose of belladonna may be taken without marked effect by an infant, and yet the same dose produce toxic phenomena in an older child; and in like manner we notice the same want of uniformity in the effects produced by opium and its alkaloids. The administration of both belladonna and opium, however,

plays so great a rôle in the treatment of diseases of infancy and childhood that cases where any approach to toxic symptoms have occurred when these drugs have been used, should immediately be put on record. In this way we shall, by degrees, learn to know what are the danger-signals and what limits we should hesitate to pass beyond at a given age. These records will also be of use in encouraging us not to despair of saving the patient's life in cases where the amount of the drug taken seems very formidable.

During my term of service at the City Hospital in 1891, a little girl, nine years old, was brought to my wards at 10 P. M. At about 7 P. M. on the same evening, the child stated that she had drunk part of the contents of a bottle containing a solution of atropine, two grains to the ounce. An emetic of mustard and water was given to the child at 9 P. M., before coming to the hospital, and this had produced free vomiting. The child, on entrance to the ward, was partly unconscious; pale; pulse 120, of good strength and regular; respiration regular, quiet and about normal rate; temperature 99°; tongue coated and dry; pupils widely dilated and not reacting. Convulsive movements chiefly confined to the upper extremities occurred at times. The urine was of a normal color, acid, specific gravity 1020, no albumen. The case did not appear to require any treatment by drugs.

On the following morning the child was comfortable with the exception of a slight headache. The pupils were still widely dilated. The urine was passed naturally. Three days later she was well and the pupils were reacting naturally.

The sister of the child just spoken of was brought into the hospital at the same time and with the same history and was placed in the wards of Dr. J. G. Blake. This little girl was four years old. She had been given an emetic two hours after drinking the atropine solution, and one hour before entering the hospital. The face was markedly flushed: the pupil of the left eye was fully dilated and did not react to light. The right pupil, which was the seat of an old iritis, did not dilate; the pulse was 160, regular, rather full and compressible; respirations 28, regular and quiet; temperature 100°. Every few minutes the patient had mild, clonic convulsions, affecting chiefly the muscles of the arms, legs and face. They were of short duration.

As the patient was in the stimulant stage of the poison, with convulsions, she was given two minims of Magendie's solution, subcutaneously. After a short time the patient quieted down and went to sleep. By midnight the respirations had fallen to 22, the pulse to 130 (of good strength), and the patient was quiet. On the following morning the pulse was 92 and the respirations 18; the child was drowsy and fretful and the pupil still dilated. Three days later the child seemed well, and the pupil was gradually contracting.

One-half to one grain of atropia has been considered a fatal dose for an adult so that the amount of atropia in the solution (two grains), presumably swallowed by these two children would appear to be a serious dose to be disposed of. The probability is that they did not get a grain each; but the bottle had only had a few drops taken out of it before they got possession of it, and was found empty after they both said they had drank some of its contents. The usual history, I believe, of belladonna or atropia poisoning is that the patients recover; and it is on this ground that the

¹ Read before the Obstetrical Society of Boston, January 9, 1892.

drug has been formerly used with such freedom (to the extent of tonic symptoms) in France in the treatment of pertussis.

Dr. Blake's patient was treated with the supposed physiological antidote of atropia, morphia; mine had no medicinal treatment, in accordance with certain opinions that morphia is not indicated in these cases.

A little girl, two years old, was brought to the Children's Hospital during my service, in the morning at ten o'clock, by her father, who said that the mother had tried to poison the child in the night by giving it a teaspoonful of laudanum. It had vomited the laudanum, and the same dose was then repeated and possibly some more later.

The child was cold; temperature 97°; pulse slow, about 50-60; respirations 6 to 10 in the minute; pupils tightly contracted, not reacting; child semi-conscious. Atropia ($\frac{1}{10}$ gr.) was given subcutaneously, and the child kept continually moving by relays of nurses, who slapped it and applied electricity. Strong coffee, in teaspoonful doses, was given every hour, and the atropia repeated, with intervals of about three hours, twice. The child gradually grew brighter towards evening; the pupils dilated widely; a rash came out on the chest; and the child in a day or two was entirely well.

In connection with these cases I found of considerable interest, the examination of an infant five months old, whom I was called to see in consultation; the diagnosis had been made of tubercular meningitis.

The history was that of a healthy, breast-fed infant with a healthy mother. For two weeks there had been symptoms of fretfulness, probably caused by the teeth. Had had a cough and cold in its head for two days, and on the second day had been much more restless, and in the afternoon screamed a great deal. A mixture of fifteen drops of laudanum in thirty teaspoonsfuls of water was ordered, and during the night it was given teaspoonful doses. During the night the hands and feet were reported to be cold and the baby to be almost unconscious. On the following day when I saw it, it had contracted pupils, cool skin, temperature 98° F. (rectal), fontanelle a little depressed. Pulse 120, regular; respirations quiet, not especially slow. Did not notice, but could be roused, and would then cry vigorously and as though it were freiful at being disturbed.

The attending physician had already told the family that it was a case of tubercular meningitis, and had ordered the laudanum to keep it quiet; it was supposed to have taken eight teaspoonfuls (four drops of laudanum). I advised atropia ($\frac{1}{10}$ gr.), which was given at once by the mouth. Four hours later the pupils were reported to be somewhat less contracted, but reacting very sluggishly; an hour later another dose of atropia ($\frac{1}{10}$ gr.) was given, and the pupils then dilated, the infant grew brighter and recovered, with an efflorescence (probably from the atropia) on the chest and face for a few hours.

A little girl, seven years old, was given what was supposed to be thirty-five drops of paregoric at 3 A. M. At 6 A. M. it was noticed that she breathed heavily, and at 7 A. M. she could not be aroused. I saw her at 8 A. M., when, although very sleepy, she could be aroused. The pupils were contracted and did not react; the pulse was rather slow; the respirations natural. She was made to vomit freely, and belladonna was then given in the form of tablets (ten

minims). No result was obtained from the belladonna; and during my temporary absence Dr. S. E. Wyman took charge of the patient, and gave her atropia ($\frac{1}{10}$ gr.) subcutaneously, at 10.45 A. M. The pupils then dilated, and she made a rapid recovery.

An analysis made by Prof. William B. Hills showed that, instead of the supposed paregoric, the thirty-five drops contained fourteen one-hundredths of a grain of morphia.

In my service at the Infant Hospital, I meet every year with young infants who have been drugged with small doses of opium, presumably paregoric. The drug when first given them in their homes has quieted them; but larger doses becoming necessary to keep them from crying, the parents become alarmed, as they can only be quieted by the drug, and they are sent to the hospital for treatment. Their advent destroys the peace of the wards for usually four or five days. They cry loudly and continuously, and only shut their mouths to swallow their food. They are usually considerably atrophied, and show gastro-intestinal disturbance; but they evidently are not in pain, and are crying for what they crave for, paregoric. This, if offered to them, they will take with far greater avidity than their food, but it only excites them to still greater clamor. The treatment is to absolutely withhold the drug from them, and after a number of days they apparently forget all about it, and soon begin to eat, grow and behave like other babies.

I mention this class of cases to possibly aid the physician in detecting them, where in private practice the nurse may be offsetting the good effects of a carefully prepared food, by giving a few drops of paregoric at night to insure the sound slumber of her charge.

ASTIGMATISM AS AN ELEMENT OF REFRACTION, AND ITS OBJECTIVE STUDY BY THE OPHTHALMOMETER OF JAVAL AND SCHIOTZ (MODEL OF 1889).

BY EDWARD SWASEY, M.D., OF WORCESTER, MASS.

Last Assistant Surgeon to the Manhattan Eye and Ear Hospital, New York City; Fellow of the New York Academy of Medicine.

THE student of the current ophthalmic literature of the present day will not be obliged to read very far on the subject of refraction and its errors to observe how prominent a place is being given to astigmatism as an element of these errors. Although the subject is an old one, and it is now a hundred years since Thomas Young first made a study of the subject in his own person, and it was christened with its present name by Whewell, in 1846, nevertheless, the last word is not yet spoken on astigmatism. Some of our most experienced ophthalmologists of to-day are studying the subject with more care than was formerly bestowed upon it, carefully noticing small fractions of a dioptre of astigmatism, and the axis of the meridian, and prescribing weak cylinders, where, a few years ago, these were not looked for, or, if found, were ignored. But it is just the correction of these apparent trifles, in many cases, that is giving our patients a great deal of relief, and ourselves a good measure of satisfaction. Probably if the whole truth could be known of the past and present failures, or only half-satisfactory results, in prescribing glasses for the relief of the various forms of asthenopia, this one element of astigmatism has been, and still is, the one sly fox that is most

difficult to run to ground. He it is who most persistently eludes our grasp, plays fast and loose with our best-laid schemes, and leads us into many a provoking decoy. Or, as Fox and Gould ("Diseases of the Eye") state it: "Astigmatism is an invisible and elusive imp of mischief, requiring much keenness and patience to hunt him down. His hiding-place is the ciliary muscle; his disguise, amblyopia."

Is it to be inferred, then, that because we are hearing and reading more of this trouble of late years that it is on the increase? Formerly hypermetropia, pure and simple, and uncomplicated myopia, were believed by many ophthalmologists, not all, however, to stand in the fore-front of the troublesome enemy, and many and many are the cases reported where no mention is made, or record given, of astigmatism, but simple spherical glasses were given, and most gratifying results soon followed, or were reported to have followed — proving again that we can find almost anything we are looking for, if we have a belief that we wish to establish. Just now the muscles external to the globe, and astigmatism are standing forth to be counted, and as rivals for first place. The muscles are making the most noise, to be sure, but it is the astigmatism that is doing the most mischief.

Probably, we cannot say that astigmatism is increasing, but perhaps our knowledge of it is improving. It undoubtedly can be said with truth that a nervous irritability, a neurasthenia, of the Americans is being more and more noticeable in the last ten years. And since la grippe has worked its peculiar work over nearly the whole of our country, there are many thousands who are finding themselves reduced in vital force, and unable to withstand many little ills and pains that before they took no note of. How often do we hear at the bedside, in our offices, and on all sides, the expression, "Since I was ill with la grippe!" And since that time some trifling pain or distress has become a thorn in the flesh."

Dr. J. J. Chisolm, of Baltimore, in a paper read at Washington, in May, 1891, advocating the use of low grades of cylinders, formulates this axiom: "Headache under eye use, with acute vision, in by far the majority of cases, means astigmatism, and usually of a low degree. . . . I often wonder what has become of the hosts of hypermetropic eyes that I formerly saw and treated with spherical convex lenses. . . . The same class still come to me from other specialists, who are holding the views that I formerly acted upon before I found out my mistake."

Dr. W. F. Mittendorf, of New York, in a paper in the *Medical Record*, July 18, 1891, gives his testimony in favor of giving cylinders of as low power as one-half or one-quarter of a dioptric in many cases of asthenopic headache.

Dr. L. S. Dixon, of Boston, has "long been an intense believer in the benefits resulting from the correction of very small errors of refraction, particularly of astigmatism."¹

But I presume no one would advocate such careful and exact correction of uncomplicated hypermetropia or of simple myopia as is indicated by these quotations regarding astigmatism, showing that the tendency is to promote this latter fault to a more and more important place. Moreover, it is being studied objectively in the last few years, and this has always been a more exact and trustworthy method in the science of medicine than

the subjective method. For example, compare our knowledge of diseases of the heart and lungs since auscultation and percussion became a branch of our science with the period when subjective symptoms and examinations were relied upon. Consider the fine shades of distinction the neurologist can now make in his differential diagnosis by his objective study of his cases, rather than by a subjective examination. Likewise, how much now can be learned in renal diseases of our patients' condition, though no questions be asked! So, in some measure, at least, the modern methods of objective study in ophthalmology is advancing this branch of medical science. Noyes says: "The more we can rely on objective methods the better." The objective methods most in use are, of course, the ophthalmoscope and the ophthalmometer. Some ophthalmoscopists claim they can detect an astigmatism as low as 0.25 dioptric, and locate its axis. Whether they can do this or not it is fully acknowledged by our best authorities that it is almost impossible of accomplishment, and it is not claimed by the vast majority of examiners. We must look through the lens, and unless full mydriasis exist, it is difficult to exclude accommodative effort on the part of our patient, to the exactness of fractions of a dioptric. The other method is by the ophthalmometer, and it is this instrument that shall most interest us in this paper.

It may be well to review some of the chief features, and study some recent statistics of astigmatism at this juncture. Very few, indeed, are the cornea that are perfectly symmetrical and of equal curvature in all their meridians, and it is a well-recognized rule that there is a "normal astigmatism" of from one-quarter to one-half of a dioptric. The two meridians of the cornea which differ from each other in their curvature, and likewise in their refractive powers, are called the *principal meridians*. They are the vertical and the horizontal, or nearly in these planes, and stand at right angles to each other, and are the meridians of greatest and least refraction.

The vertical has a shorter radius of curvature than the horizontal, and a ray of light passing through it comes to a focus at a point anterior to the focal distance of a ray passing through the horizontal, which is the meridian of lowest refraction. Or, in other words, the focal distance of the vertical meridian bears a similar relation to the retina as does the hypermetropia eye — it is too short: while the horizontal bears the relation to the retina of the myopic eye — it is too long. This is the law, but to it there are exceptions. The axis may vary from the vertical to either side to the amount of 40°, and likewise from the horizontal. But the law holds good even then, that the meridians of unequal refraction will stand at right angles to each other. We have astigmatism "with the rule," when, in the hypermetropic the correcting plus cylinder stands at 90° or vertical; and in myopic astigmatism the minus cylinder is at 180°, or horizontal.

But where, in a case of hypermetropia astigmatism, a plus cylinder can be used only at 180°, or in a case of myopic astigmatism a minus cylinder can be used only at 90°, and in either example we have "astigmatism against the rule."

Mittendorf, in the paper referred to, examined one thousand cases of refraction. Of these, there were 111 cases of simple myopic astigmatism, and 626 cases of simple hypermetropic astigmatism. Of all kinds of astigmatism the amount reached as high as 83 per

¹ New York Medical Journal, March 28, 1891, page 333.

cent.; 119 of myopic, and nearly 700 of hypermetropic, astigmatism. In the hypermetropic cases the astigmatism was with the rule 418 times; against the rule, 33 times. In the myopic cases it was with the rule in 80 cases, against the rule in 21 cases.

In 1888 Dr. Swan M. Burnett, of Washington, examined by Javal's ophthalmometer 576 healthy cornea. Of these the horizontal meridian was of lowest refraction (astigmatism with the rule) 420 times; the vertical was of lowest refraction (astigmatism against the rule) 20 times.

In 1886 Dr. Kelch, of Louisville, Ky., published examinations on 512 cases of astigmatism, taken from the records of Dr. Dudley S. Reynolds, of Louisville. In the right eye 448 cases, in the left eye 452 cases. In the former cases the astigmatism was with the rule 377 times, in the latter cases it was with the rule 374 times.

Referring again to Burnett's interesting statistics, we find in his 576 cases there were but 55 cases of simple myopia, while of myopic astigmatism there were 140 cases. Simple hypermetropia was present in 59 eyes; hypermetropic astigmatism in 96 eyes. In 55 eyes there was compound hypermetropic astigmatism, and in 36 eyes compound myopic astigmatism; in eight mixed astigmatism. In Mittendorf's cases there were 111 cases of simple myopic astigmatism; 626 cases of simple hypermetropic astigmatism, and of mixed, 21 cases. The law regarding the axes of the principal meridians holds good, also, in cases of compound hyperopic, and compound myopic, astigmatism. But the cornea alone is not the only seat of this refractive error, for the lens participates in some small degree in a certain per cent. of cases, and the combined corneal and lenticular trouble gives us the "total astigmatism."

Javal says that corneal astigmatism almost always represents the total astigmatism. In but four eyes of Burnett's 140 cases of myopic astigmatism, was the total astigmatism greater than the corneal; in 11 it was less. In his 96 cases of hypermetropic astigmatism the corneal was greater than the total in four cases; in two it was less. The corneal astigmatism was against the rule in 18 cases, while the total was against the rule in 42 cases. The lenticular astigmatism is due to some oblique position of the lens, or some lack of symmetry in its outline, and also through an effort of accommodation which is more or less constantly going on in the ciliary muscle and lens to make amends for this trouble at the very threshold—the corneal astigmatism. And again, nature has tried to adjust the internal arrangement to correct the corneal trouble, for the meridian of greatest lenticular refraction is more often horizontal than vertical; whereas, as we have seen, the opposite condition prevails in the corneal astigmatism.

It is well known that the accommodation is much more active and important in hypermetropia than in myopia, so it is in hypermetropic astigmatism over the myopic. Hence it is in young subjects, while yet the lens is plastic and the accommodation active, that quite a degree of astigmatism can be, and often is, covered up. But let debilitating sickness come and the accommodative power, like all muscular force, be depressed, and at once this hidden fault of the cornea is revealed. Likewise as middle life approaches, the hardening of the lens, incident to this period, curtails the accommodation power, and again a small amount of astigmatism,

unknown before, begins to be troublesome. And yet all through life it is the lower grades of astigmatism that keep up the more persistent effort of the ciliary muscle, and maintain the conflict between the powers that be and the powers that would be. In the higher grades the retina has always been accustomed to the blurred outlines and distorted figures, and accepts them with but little rebellion. The lower grades, also, are not incompatible with good distant vision, before the middle period of life approaches, but accommodation must be used to accomplish this. Javal himself had astigmatism equal to 2.5 dioptres, but at the age of twenty-four could see the stars distinctly. Dr. Chisolm, in the article referred to, says: "I find vision $\frac{2}{3}$ in one-third of my astigmatic cases, and this good vision among my most suffering patients. The most marked relief, and the most brilliant results from the adjustment of cylinder glasses, I obtain among this class." We have all, I presume, seen very many cases, that would not accept a cylinder, even of low grade, kindly, or be improved by it for distant vision, yet in reading and in near work received a great deal of relief with this same cylinder.

And it is in just such cases that the objective methods, and especially by the ophthalmometer, are shown to be superior to any subjective examination. The ophthalmometer of Javal and Schiötz (model of 1889) leaves little to be desired in the instrument. So accurate and rapid is it in its operation that many a time in a good light have I measured the astigmatism in dioptres, and located its axis in both eyes in two minutes by the watch. Dr. H. B. Noyes, of New York, says of it: "During the past four years I have constantly made use of it in my private practice and can commend it very greatly. . . . For rapid work, and especially in public institutions, this instrument is invaluable. For the young, the confused, the dull, the amblyopic, it is most excellent." Burnett, of Washington, considers it one of, if not the, most important instrumental means for the diagnosis of astigmatism.

Dr. D. B. St. John Roosa, of New York, says of it: "All the previous methods of determining the existence, degree and axis of astigmatism, after twenty-five years of experience, I consider much inferior to this."

This instrument will certainly detect any corneal astigmatism that may exist; if we fail to rightly interpret it or its angle, and give relief, these are not the faults of the instrument. From my experience with it for the past two years, in public and private practice, I believe it to be a very reliable and accurate indicator of corneal astigmatism, both of the amount and of the axis. I am more and more inclined to follow its readings closely, more closely, perhaps, than the accepted rules call for. The rule given by Dr. Bull, of Paris, is: Give the patient, in astigmatism with the rule, 0.5 dioptre less than the instrument indicates; and in astigmatism against the rule, add 0.75 dioptre to the findings. Dr. Burnett in his latest article² on this subject thinks Dr. Bull's allowance of three-fourths of a dioptre too high for the majority of cases. In this same article Dr. Burnett speaks in the highest praise of the ophthalmometer and has nothing to retract from his former praise of it. In an article³ by Dr. Carl Koller (the discoverer of cocaine anesthesia)

² Journal of American Medical Association, September 5, 1891, page 234.

³ Ibid., September 13, 1890, page 380.

thesis) on this same topic, the highest praise is bestowed on this instrument in the study and treatment of astigmatism. This observer believes that astigmatism produced by tilting of the lens to an oblique position, and producing a constant, static factor, "is comparatively a very rare thing." But that dynamic astigmatism, produced by irregular contraction of the ciliary muscle, is most always the variety present. This tilting of the lens was assumed by Tscheiring. Bull also believes it is the explanation in many cases. In the opinion of Dr. Burnett it "is much commoner than is generally allowed, particularly as a corrective of the normal astigmatism of the cornea." It is a subject on which a difference of opinion exists, and it must be studied carefully to determine the question first objectively, afterwards subjectively and under full mydriasis.

But we have seen by the foregoing statistics, and by Javal's statement, how nearly the corneal astigmatism represents the total. If then we have an instrument that accurately measures the former, why may we not expect relief from the whole trouble after a short interval of use in which the accommodation is quieted and relieved? It is believed that the tilting of the lens does not occur in a large per cent. of cases, while accommodative effort does exist very largely. And for this reason, I say, I am inclined to depart from these rules, somewhat, especially in the lower grades of astigmatism, and when I am trying to give relief to asthenopic symptoms on near work. For example: A book-keeper, aged thirty, vision each eye $\frac{1}{2}$, H. M. each eye 0.25. Javal showed in right eye 0.50 dioptr, axis 90°; left eye hardly 0.50 dioptr, axis 90°. Ophthalmoscope showed about one dioptr of hypermetropia. Glasses were given as follows: right eye, + 0.25 S. ∞ + 0.50 cylinder, axis 90°; for left eye + 0.50 S. ∞ 0.25 cylinder, axis 90°. He reported ten days later, having used these constantly for writing and reading, the greatest relief at his work. The blepharitis of some months' duration had almost wholly disappeared. He was now reading with comfort in the evening, a pleasure he had been obliged to forego for months; and, as he expressed it, he supposed he must continue to look from his books at short intervals to give his eyes relief, as he had been doing for a long time. But no such inclination existed now and he could continue at his work uninterrupted. It may be said this man would have received equally good results had I given him a + 1 D. spherical. Possibly; but it may be said, also, he would have been made comfortable had I given only the cylinders. But certainly with the combination he was made happy, which is quite enough for him and for me to know.

Or, another example: A patient, age twenty-nine, vision = right eye $\frac{1}{2}$, H. M. 0.25; left eye $\frac{1}{2}$, no H. M. Javal showed no astigmatism in right eye, and 0.50 D. in left, axis 120°. I remarked that I found a trifle more error in the left than in the right eye. He said it was always the left eye that first became painful and gave him the most trouble in his near work. It will be noticed the angle is at 120°; but he would accept even this weak cylinder at no other angle. But in patients who have astigmatism against the rule, more asthenopia is caused by low grades than in the higher grades that are with the rule. This patient received great relief in reading and all close work by the use of these glasses, which were as fol-

lows: right eye, + 0.50 S.; left eye, + 0.25 S. ∞ + 0.25 cylinder, axis 120°.

Again, in a book-keeper, aged thirty, the vision was right eye $\frac{1}{2}$ H. M., .75 D.; left eye the same; glasses over both eyes, H. M. was 1.25 D. Javal showed 0.50 D. in each eye, axis 90°. This patient had been troubled with headaches in back of head and neck for months, and had been for some weeks under treatment for dyspepsia, believing the headaches came from this. No relief came from this treatment. He was given glasses for near work as follows: right eye, + .75 D. ∞ + 0.50 cylinder, axis 90°; left eye, same. After having used the glasses ten days at his near work he reported that from the first the headaches left him completely, and he had been entirely free from them since. There was no blepharitis in this case.

A girl, age ten, had a well-marked convergent strabismus of right eye. This patient had 4. dioptres of astigmatism in right eye, axis 90°, and 3.50 dioptres in left. She has worn glasses for four or five years, given by one of Boston's most careful ophthalmologists. And yet these were simple spherical lenses of four dioptres, and the parents had never heard of astigmatism. The ophthalmoscope showed four dioptres of hypermetropia. She has worn glasses of + 2. D. ∞ + 3.75 cylinder, axis 90°, on right eye, and on left + 2. D. ∞ 3.25 cylinder, axis 90°, for three weeks with great relief to headaches from which she suffered. Surely, with the ophthalmometer no one would fail to detect this high degree of astigmatism. It is rather remarkable that in four children in one family, a boy aged twelve, another aged fifteen, a girl aged eighteen, and sister aged twenty-four, all being myopic, that all should have astigmatism against the rule, as indicated by Javal, and subjectively they would accept a plus cylinder only at 180°, or a minus at 90°.

I have given these few examples as members of a class in whom, I think, we may follow the instrument more closely than Dr. Bull's rules indicate; and also to show how the ophthalmometer starts us on the right course in our examinations. Moreover, some competent observers believe more serious mischief than asthenopia may, and sometimes does, follow uncorrected astigmatism. The observations of Scheen show that strain of accommodation in astigmatism may be productive of glaucoma and cataract. Dr. Samuel Theobald, of Baltimore, found that where the meridian of least refraction was vertical (astigmatism against the rule), this variety of astigmatism was in almost every instance associated with glaucoma. He believes that the slightest degree of astigmatism of this character almost always gives rise to trouble, and if it amounts to not more than 0.25 D. requires to be corrected. Hyperemia of the ciliary body is particularly active in this form of astigmatism. This causes an increased flow of fluid into the vitreous, and let the drainage of the anterior chamber be a little at fault, and we have all the required conditions for glaucoma. Dr. Roosa tells us that Professor Fanas, of Paris, believes that astigmatism is usually the exciting cause of strabismus, and I know personally that Dr. Roosa himself shares in this belief.

If, then, all cornea be irregular, must all eyes have cylinders before means? By no means; but in eyes with good distant vision, and which are obliged to do close work, and in which blepharitis and congestion exist, and perhaps also more pronounced asthenopia, if

astigmatism is found even in small degree, I believe in fully correcting it in the glasses we give for close work.

Some of the advantages pertaining to the use of Javal's instrument have already been spoken of, but the chief advantage of all is that it does away with the use of atropine, or any other mydriatic, in the vast majority of cases. I know this statement will not be, and is not, accepted by many ophthalmologists. But those who have used the instrument the longest time and most carefully are the ones best qualified to pass an opinion. Certainly, if it be true that atropine need be used only infrequently rather than commonly "it is a consummation devoutly to be wished." This is the one feature of examination for refraction that patients detest at, both from loss of time and the great annoyance it occasions. The cornea is the seat of astigmatism, but the cornea is not symmetrical in its various meridians, and a difference in curvature exists, also, between the central and the peripheral portions, being more sharply curved in the central than in the peripheral portion. Is it rational then to try to hunt down any small error like this by bringing a much larger area of the cornea into the field of vision than is ever found there in a normal, healthy pupil? But mydriasis does this unavoidably.

Some of our best observers speak of using a mydriatic in testing for astigmatism as follows:

Landolt says: "We very seldom have recourse to atropinization for the determination of astigmatism."

Dr. John Green says: "It has been the practice of the writer to abstain from the use of atropine in measurement of astigmatism, except in a few cases of special difficulty, and never to adopt a measurement made under full mydriasis until it has been verified or corrected by other tests, made after the pupil has returned to its normal size."

Dr. Mittendorf says: "In the lesser degrees of astigmatism atropine should never be used, as the results obtained are often misleading, and I have often found that not only the strength but even the axis of the cylinder, determined under atropine, will not be accepted by the patient after the effects of the mydriatic have disappeared."

Dr. Roosa, in speaking on this same subject in connection with Javal's ophthalmometer, says: "A release from the use of atropine and so forth is afforded by the use of Javal's ophthalmometer. In the hands of those who have carefully practised its use, it simplifies the problem of the determination of astigmatism very much. . . . To use the ophthalmometer with exactness, however, one must spend a little time in practising with it. It is not necessary to paralyze the accommodation, except in very rare cases of spasm, and then for therapeutic purposes, if we can once exactly determine the degree of astigmatism. This is the key to the problem in the diagnosis of the causes of asthenopia; with that solved we can soon determine by the ophthalmoscope on the test letters, without the use of any mydriatic, even once, whether to advise a convex or a concave cylinder, and whether or not an additional spherical will be needed. . . . I do not now use atropine for the determination of the degrees or kind of error of refraction once, where I formerly used it thirty times."

Dr. Noyes, on the same subject, says: "The whole problem may often be solved at a single sitting and without atropine."

But ought we not to use atropine in young subjects? I would instance the following case:

A school girl, aged sixteen, had constant headache, and working over her books was impossible without great suffering. She had vision: right eye $\frac{2}{3} + \frac{1}{3}$ W. + 1.75 D. spherical; left eye $\frac{2}{3} + \frac{1}{3}$ W. + 1.75 D. spherical. Javal showed astigmatism in right eye of 0.50 dioptric, axis 90°; in left eye 3 dioptries, axis 90°. Ophthalmoscope showed 4 dioptries of hypermetropia in each eye. No atropine or other mydriatic was given, but glasses were prescribed at once as follows: right eye + 4 dioptries spherical; left eye + 1.75 D. S. C + 2.25 D. cylinder, axis 90°, to be worn constantly. She reported four weeks later at the Manhattan Eye and Ear Hospital. She had worn her glasses constantly and had returned to her studies; the headaches had entirely left her from the first, and she was enjoying her life, her books and her glasses.

If a case of this complexity and amount of refractive error in a school girl of sixteen could be relieved and made happy, without the use of any mydriatic, why may not any case?

Or, take an older subject: A lady, age forty-seven, vision: right eye $\frac{2}{3}$; left eye $\frac{2}{3}$. Javal showed 3 dioptries in each eye, axis 90°; the ophthalmoscope showed in each eye about 1.50 D. of hypermetropia. The glasses given were these: right eye + 1.50 D. S. C + 2.50 D. cylinder, axis 90°; left eye + 1.25 D. S. C + 2.50 D. cylinder, axis 90°. This lady had for years been trying to find glasses that would give her comfort in reading and sewing, and she had been examined by very good men. But the ophthalmometer revealed the whole story in less than five minutes. She assured me at the outset that she was myopic and had been for years. She uses these glasses with really the utmost pleasure, and has lately secured a duplicate of the prescription. She says it is the first time she has seen the eye of a needle, but she sees it now and wonders at its size.

I cite these few cases to show what may be done in the higher and the lower grades of refractive error and astigmatism by the employment of the modern and perfected methods of objective examination, and without the use of atropine, for in none of these cases was a mydriatic used. It is very rare indeed that I use it, but I do rely upon my ophthalmometer for the amount and axis of the astigmatism, and in a room painted dead black in all parts, with a tin tube over my gas chimney with a small opening in it through which I receive light for my ophthalmoscope mirror, I can learn the remainder of the refraction (for in such blackness the accommodation will, in a great measure, soon relax), certainly to an approximation as near as we wish to correct it.

If these principles, so hastily reviewed in this paper, are correct principles, and this method of practice has sufficient merit to be classed in such good company, it certainly saves our patients a vast deal of annoyance, and no little loss of time, and time is sometimes money. If the method is wrong I have yet to learn why it is so, or to see cause to regret the results obtained.

It is reported that an imperial irade has been issued forbidding the use of cocaine and sulphonal throughout the Turkish empire.

Clinical Department.

THE CONTAGIOUSNESS OF ERYSPIELAS.

BY WALTER REED,
Assistant Surgeon U. S. A., Fort Snelling, Minn.

In the JOURNAL of February 4, 1892, Prof. J. C. White, of Harvard, writing concerning "Some Dangers of Infection Incidental to Professional Life," says: "With regard to the contagious character of erysipelas diverse opinions prevail." Again: "Common belief has it that there is great danger of such communication, an opinion largely held apparently by our profession as well. I do not doubt the possibility of such transference, but I believe that it rarely occurs; I refer to the ordinary superficial forms of the affection. In the great number of cases that I have treated I have not known a single instance in which a second member of the family, nurse, or medical attendant has become affected."

As I have had an experience bearing directly upon the point at issue, I beg to submit it. During the fall of 1883, Lieutenant B. was attacked with facial erysipelas of a moderately severe type, the disease commencing over the bridge of the nose and spreading rapidly over the face and scalp. He was carefully nursed by Private A., who remained the greater part of the time in the room with him, and who slept in an adjoining room.

About the time Lieutenant B. was convalescent — some twenty days from the beginning of the attack — Private A. became engaged in an altercation and received a contused wound over the left orbit. This wound was dressed by the writer, the day following its receipt. The next day erysipelas appeared in the edges of the wound, rapidly extending to scalp and lower face. Now, I will admit that it would be perfectly fair to conclude that Private A. had probably infected his wound with the *streptococcus pyogenes*, which had remained on his fingers since his attendance on Lieutenant B., or that the writer had infected the wound; for we had both repeatedly applied cloths to the erysipelatous surface of the first patient.

However, be this as it may, Private A. was placed in a room by himself at the post hospital, and Hospital Attendant K. detailed to nurse him. Although this man did not sleep in the room, he virtually occupied it the greater part of the time, as the patient was troublesome and required almost constant attention.

Three weeks later, while A. was convalescing, Hospital Attendant K. was attacked with facial erysipelas and was put to bed in the same room with the second case, and Private S. detailed to nurse him.

Before Attendant K. had recovered fairly, Private S. was stricken down with the same disease and was placed in a separate room. He was nursed by Acting Hospital Steward G., who volunteered his services for this purpose. He was told that he need not remain in the room any more than was absolutely necessary to look after the wants of the patient, but as the steward had no fear of the disease, he was constantly in attendance, and spent a part of each night with the sick man.

When the foregoing cases had recovered, the two rooms were thoroughly disinfected, walls and floors being wiped down with bichloride solution, and afterwards exposed to fumes of burning sulphur.

Three weeks from the commencement of Private

S.'s case, which had not been severe, Acting Steward G. was attacked with facial erysipelas of a very severe type, and came near dying.

As there seemed to be no end to this succession of cases transmitted from patient to attendant, I requested the detail of four men to nurse this latter case; each man to be on duty six hours, and during this time to remain in the room as little as possible; free ventilation of the room to be enforced, and while off duty to remain in the open air as much as possible. Under this system of nursing, our little epidemic ended.

There had been no cases of erysipelas at the station prior to Lieutenant B.'s case, and none occurred during the following seven months of my stay at the post. I believe that the second patient would have had the disease, even had he not suffered any traumatism. I think that this conclusion is perfectly justifiable in the light of the occurrence of the subsequent cases, without any break in the integument. I know not how the *streptococcus pyogenes* gained access to the circulation of those patients. Each case began with soreness and congestion of the pharynx with some swelling of the lymphatics of the neck. This was slight and soon subsided. There was no formation of abscesses beneath the skin, except in the last case, in the loose tissue around the left orbit. All were young men in the prime of life.

Looking at the matter from my standpoint, I should say that there is good cause for the common belief that erysipelas can be communicated from patient to attendant.

TWO OVARIOTOMIES.

REPORTED BY BENJAMIN D. GIFFORD, A.M., M.D., CHATHAM, MASS.

Two cases of ovarian cysts which came under my observation during the second week in December, 1891, for the removal of which laparotomies were performed, illustrate in a remarkable manner the value of this operation, not only when undertaken for the deliberate cure of the affection, but also as a means of saving life when the conditions appear unfavorable and the patient evidently about to die.

The first case, that of Mrs. H., age thirty-six, childless, was one in which peritonitis was present and threatened life. She had been to Boston and had undergone a somewhat rough handling in the repeated examinations which she had received in a public clinic, and after a ride of nearly one hundred miles home was taken with a chill, which developed a peritonitis. This was of an active type, generally diffused and sufficiently severe to call for the gravest apprehensions for her recovery. Under the circumstances I advised an operation as the means best calculated to give her a chance for life. Accordingly I telegraphed for Dr. Henry O. Marcy, of Boston, who came down and operated. The tumor, which weighed sixteen or eighteen pounds, was located on the left side and was everywhere adherent, both to the abdominal walls and to portions of the intestines by recent lymph. The most noticeable thing about it was the fact that the tumor had been completely twisted upon its pedicle, and the entire growth external to the constricted neck of the cyst was gangrenous. The pedicle was sewed across with kangaroo tendon, and a sufficient amount of peritoneum was dissected from it to be intra-folded over the stump, and was secured by a continued Lem-

bent tendon suture. The peritoneal cavity was closed with a continuous suture of fine tendon, and the abdominal wound joined by a series of stitches which brought its margins into close relation from bottom to surface; the skin closed by a blind suture and iodoform collodion applied. This patient made a most excellent recovery, without a single untoward symptom.

The second case, that of Mrs. A., age fifty-six, had, up to the time of the operation upon the preceding case, been under the care of an advertising doctor in Boston who was undertaking the rather unique method of removing the tumor by emetics and purgatives. This treatment had rapidly exhausted her strength and she was fast travelling toward the grave. Encouraged by the brilliant success of the operation for the relief of her friend and neighbor, Mrs. H., she besought me to take her under my care and make such arrangement for her treatment as was deemed best. Upon visiting her I found her sitting propped up with pillows, short of breath, and the picture of distress. Her abdomen was immensely enlarged and her limbs enormously distended; pulse small and quick. Death would evidently soon come, unless relieved. I again invited Dr. Marcy to come to my aid. Upon opening the abdomen the cavity was found full of fluid, due to a large rent in the ovarian cyst. Adhesions were everywhere present and considerable hemorrhage resulted from their detachment. The pedicle was cut off as usual, overcovered with peritoneum, and sewed across with continuous kangaroo tendon. Hot water was freely poured into the abdominal cavity for the arrest of the hemorrhage. The peritoneum and abdominal walls were closed as in the preceding case with buried animal sutures. The lips of the wound were sealed with iodoform collodion and a bandage applied. As in the preceding case the patient's condition and comfort were immediately improved. From a condition of impending death she was placed in one of safety and mental tranquillity. The tumor removed from this patient, fluid and solid, weighed over forty pounds.

At the present writing, six weeks after operation, both these patients are doing well.

Medical Progress.

NOTES OF PROGRESS IN PHYSIOLOGY.

BY JOSEPH W. WARREN, M.D.

(Concluded from No. 7, page 170.)

The influence of various different alcohols on the heart was examined some time ago by Dr. Hemmeter.⁹ Blood containing small amounts of the alcohol under investigation (usually 0.2%) was sent through the heart, and the action on the work done by that organ was noted. The work done is measured as the quantity of blood pumped round in any given time, let us say thirty seconds. The heart is isolated by Martin's method, which was sufficiently described in a former report, and these experiments were done under Martin's supervision. As the animals (dogs) were approximately of the same size, the quantities of blood pumped round in a given time and the change in these under the action of the alcohols would seem to be

⁹J. C. Hemmeter: On the comparative physiological effects of certain members of the ethyl alcohol series (CH_3O to $\text{C}_5\text{H}_9\text{O}$) on the isolated mammalian heart. Studies from the Biological Laboratory of Johns Hopkins University, IV, 225.

fairly comparable. The conclusions reached are summarized as follows: (1) The physiological activity of the group (CH_3O to $\text{C}_5\text{H}_9\text{O}$) increases with the complexity of the molecule, with exception of the second member, namely, ethyl alcohol, which is weaker than methyl alcohol. (2) The physiological activity increases as the temperature increases.

The effect of the alcohols is also tabulated by the author according to the *average lessening* of the amount of blood pumped out during thirty seconds as follows:

1. Methyl alcohol (CH_3OH)	.	.	19.46 c. cm. decrease.
2. Ethyl " ($\text{C}_2\text{H}_5\text{OH}$)	.	17.45	"
3. Propyl " ($\text{C}_3\text{H}_7\text{OH}$)	.	79.70	"
4. Butyl " ($\text{C}_4\text{H}_9\text{OH}$)	.	161.12	"
5. Amyl " ($\text{C}_5\text{H}_{11}\text{OH}$)	.	322.32	"

The amount for the amyl alcohol is calculated from the observations made with weaker solutions or for a shorter time, it being impossible to keep the heart going with a 0.2% solution of this alcohol so as to measure the outflow for thirty seconds. The table shows a very remarkable uniformity of increase of the weakening action of the alcohol as the number of CH_3 increases. With the exception of the ethyl, or common alcohol, the effect of each is found to be twice as bad as that of its predecessor in the series. In fact, this uniformity is almost suspicious, and one objection may be fairly urged against it. It may be questioned, namely, whether it be proper to compare the mere amount of lessening of the outflow. This is apparently done on the assumption that the amount of blood sent out by the hearts of dogs of about the same size will be comparable, and therefore the diminution of this amount in each case may be compared with that of any other case. Unfortunately the figures published in the article we are considering do not justify this proceeding. In the few cases printed as typical ones the normal amounts, that is, those pumped at fairly normal temperatures, without alcohol, range from 135 to 197 c. cm. It follows, therefore, that lessening the amount by any number of cubic centimetres will have a different significance according to the size of the non-alcoholized outflow. As only about one-fifth of the successful experiments are published, it is impossible to say what the result would be if the percentages of change under the influence of the alcohols were tabulated. Some such method would seem to be much fairer than the one tabulated above. I have calculated the percentages for the five experiments given in detail. The percentage diminution of the alcohols in the order of the table already quoted is 11.4, 15.5, 47.2, 83.4, and 199.0% respectively. By a loss of 199% is meant that amyl alcohol causes a loss of 99.5% in 0.1% solution, and this is doubled to make it comparable with the other alcohols which were used in solutions twice as strong. The percentages are not as strikingly uniform as the figures in the author's table.

Hemmeter calls attention to the peculiar behavior of ethyl alcohol, which, according to his table, is the least deleterious of the series, and altogether fails to act on the heart as it should according to its position chemically. He is accordingly obliged to resort to the hypothesis that this alcohol is "probably constantly present in minute quantities in the atmosphere, as fermentation is going on in many ways and places, and as dogs probably must frequently get some little ethyl alcohol in their food" and that an organism may "es-

tabish a special degree of tolerance of one alcohol while retaining its sensitiveness to others." He also finds it necessary to use the alleged, but, by no means convincingly demonstrated, presence of alcohol as a normal constituent of the tissues to explain the feeble action. Other observers seem to have found that ethyl alcohol acts more feebly than methyl alcohol, or, at least, does not act twice as strongly as it would if the differences depended upon the number of CH_2 elements in its composition. Probably the relations of one CH_2 to another CH_2 , or to several of them is of more consequence than the mere number of them, and this view would permit the latter three alcohols of our series to have a much more vigorous action than the first two. In the meantime it would be interesting to have a revision of Dr. Hemmeter's figures in the manner suggested, for the percentage method does not put ethyl alcohol in quite so peculiar a position as he has given it.

OTHER CONTRIBUTIONS TO THE PHYSIOLOGY OF THE HEART.

While there is commendable uniformity in explaining the cause of the second pair of the four heart sounds — or more exactly the second and third of the three sounds — the nature of the first sound still provokes discussion and invites experiment. The latest communication is by Haycraft,¹⁰ and presents considerations in favor of its valvular character, or at least of a definite valvular element. He admits that the contracting ventricle may produce a sound, but maintains that this sound is a resonance sound — and moreover a very complex one since it includes chest, stethoscope, and ear resonance tones. An examination of the pitch of the heart sounds seemed to show that they are higher than those produced by contracting skeletal muscles — or by the muscular tissue of the pulsating but bloodless heart itself. The pitch of the two heart sounds was determined for rabbits, a dog, and a boy by three persons with good musical ears. It was found that the heart sounds varied "somewhat in pitch even in the same species, but they are always in the bass clef and separated a minor third, or an impure minor third, from one another." Haycraft then proceeded to compare the pitch of the two heart tones in excised dead hearts where, of course, no muscular contractions occurred, but where closure of the valves could be produced by changes of pressure. He used the hearts of sheep and calves and sent a stream of saline solution in through the aorta to close its valves, and also into the right ventricle so as to close the corresponding auriculo-ventricular valves. The pitch of the aortic valves was found to be about a minor third higher. Haycraft concludes: "The first heart sound is then an impure musical note, a minor third below the second sound, and in the bass clef. It is a valvular sound like the second sound. It is accompanied by resonance tones both of the chest, stethoscope and the ear, these tones being produced by the shock of the contracting heart. In addition it is of course possible that there may be concomitant sounds produced by the rushing of the blood and other minor disturbances."

In a previous report attention was directed to Martin's study of the influence of temperature upon the rate of the mammalian heart beat. He demonstrated

that "between the limits of 27° C. and 41° C., the heart of the dog, when isolated from all other organs but the lungs, beats quicker the higher its temperature, so that by heating or cooling the blood supplied to the isolated organ through the superior vena cava, the pulse-rate could be controlled."

Later experiments of the same author¹¹ have led to interesting results concerning the temperature limits of the heart's vitality. The main difficulty in previous experiments had been that high and low temperatures enfeebled the heart beat to such an extent as to interfere with its nourishment through the coronary arteries. The method by which this obstacle was removed and the pressure kept sufficiently high to ensure good nutrition need not be given in detail here.

"The isolated heart of the cat may be cooled down to a temperature of 16.5° C. (as indicated by a thermometer introduced into the right heart) and yet not be killed, as it revives if soon warmed again, but it usually dies at about 17° or 18° C." The cooling is accompanied by a slowing of the pulse.

The action of high temperatures on the heart is distinctly more complex. When the temperature is slowly and gradually raised the lethal or maximum temperature is found to lie usually between 44.5° and 45° C. Before this is reached there is found to be an optimum temperature at which the beat is quickest, although this may not be the temperature for doing the most work. This optimum in thirteen experiments ranged from 40.6° to 43.3° with an average of 41.3° C., any higher temperature in each case slowing the rate. By care it is possible to adapt the heart to higher temperatures. If the blood be cooled somewhat as soon as the heart shows any signs of weakness the temperature may then oftentimes be raised again to a still higher point without causing any weakening of the beat; in this way we can raise not merely the maximum but also the optimum temperature. This is similar to the results noticed clinically in fevers, especially in those of a markedly remittent type.

The "Baltimore method" for isolating the mammalian heart has also been used to investigate the question of the blood flow into the heart during diastole.¹² There has been much speculation concerning the "active" character of this condition of the heart. Many have believed that the blood is drawn into the heart by its own action, but no satisfactory statement had been made in support of such a view, and various experiments had made it less probable. Martin's article contains a full description of his method of working, and his results may be stated in his own words: "Once the 'aspiration of the thorax' has been eliminated [by opening the chest with the use of artificial respiration], the right auricle of the mammalian heart will not receive blood unless supplied to it under a decided, if small, positive pressure, while the heart in the closed thoracic cavity may, and probably does, act as a suction-pump, this is not due directly to an active expanding force of the heart, but is the secondary result of the pneumonic conditions prevailing within the normal closed chest cavity. Any cause diminishing thoracic aspiration must, therefore, greatly hinder the work of the heart; and it is probably more in this

manner that the circulation is impeded in certain cases of hydro- or pneumo-thorax than by direct pressure exerted on the heart itself."

What seems to be an important addition to our knowledge of the chemistry of the blood has been made by Gabritschewsky,¹³ of Moscow. Glycogen is well known to be a normal constituent of the liver and muscles, and has been commonly considered to be stored up in these organs as a sort of reserve material. The transportation of this substance from the liver to other organs is more or less mysterious because the proof of glycogen in the circulating blood has been very incomplete. Very few observers have found it in this tissue, and even these have hesitated to maintain that its presence should be considered normal.

Gabritschewsky finds that a certain small number of leucocytes normally contain glycogen. This intracellular glycogen is not much increased in man by taking food although it may be in animals. There is a marked increase in some diseases (*leukemia* and *diabetes mellitus*). Besides this intracellular glycogen there is also found free intracellular glycogen in granules or in fragments of leucocytes (Blutplättchen?). This intracellular glycogen is normal but is markedly increased in certain pathological conditions.

As already indicated the amount of such glycogen in the blood is not particularly altered by experimental feeding with carbohydrates or peptones. On the other hand, the introduction of sugar directly into the circulation or into the peritoneal cavity leads to a great increase of glycogen in the blood, and this seems also to occur when starch is injected into the peritoneal cavity. The same result is reached (guinea-pigs and dogs) when a peptone solution is put into the peritoneal cavity or into the blood. The inference appears reasonable that the leucocytes can, and do, form glycogen from carbohydrates and from peptones. The subject requires much more examination.

Some additions to our knowledge of the curdling of the blood will be mentioned in another portion of these notes below.

GASTRIC ACTIVITY OF INFANTS.

A long series of examinations of the digestive process in infants¹⁴ gave interesting results, 248 healthy foundlings thus making a slight return for the services of the State in preserving them alive. The stomachs were emptied and washed out with distilled water (35° C.) by using soft catheters (No. 8 to 10, Jaques) in the ordinary manner at intervals of ten to fifteen minutes after feeding. The ages of the babies ran from two to forty-one days. The following points are noted:

(1) After a meal of 60 to 80 grammes of milk, the stomach may be readily pumped out for one and one-half hours, but the quantity diminishes rapidly during the first hour. At the end of two hours only 20 to 30 c. cm. may be obtained, and this disappears slowly in the course of half an hour.

(2) The acidity of the infant stomach is much less than that of the adult stomach. This was tested by neutralizing with one-tenth normal soda solution using phenolphthalein as an indicator. The average results showed an increase from 0.03–0.058% [that is, 0.3 to

¹³ Gabritschewsky: Mikroskopische Untersuchungen über Glykogen im Blut. Arch. f. exp. Path. u. Pharm., xxviii, 272.

¹⁴ M. van Puteren: Untersuchungen über Physiologie der Magenverdauung des Säuglings. Dissertation, St. Petersburg, 1889. Gräbner's résumé in Jahrb. f. Kinderheilkunde, xxxi, 1890, 186.

0.9 parts in one thousand] for digestive periods of ten to ninety minutes, after which no increase of acidity was apparent. The lowest acidity observed was 0.022% while the highest, 0.121%, was only a half or a third of the amount considered normal in the adult. The determination of the character of the acid met with some difficulties since many of the more usual color reactions are uncertain in digesting mixtures of such feeble acidity. By the use of exacter methods (Riche, Rabuteau) Van Puteren convinced himself that hydrochloric acid is the normal acid in the infant stomach during the first two months, lactic acid being only exceptionally present.

(3) The antifermentative action of the gastric juice seemed to be exceedingly feeble. Plate cultures made at successive periods of the digestion showed no marked difference in the number of colonies. The conclusion is that the gastric juice of the infant is not very efficient as a germ destroyer, and the infantile digestive organs are therefore particularly prone to disturbances which, however, may be for the most part prevented by the use of sterilized milk.

(4) The milk-curdling ferment (which Foster now calls "rennin") was always absent in children up to twenty-four days, and could only be definitely demonstrated at thirty to forty days of age.

Van Puteren's results as to the peptonization process itself do not seem (judging from the abstract) sufficiently exact to be very interesting. Albumin (by which is presumably meant a substance coagulable by heat) has generally disappeared by the end of the first hour, and "pepton" is constantly present twenty-five minutes after feeding and until the end of the digestive process. Sugar was always found, and fat, too, so long as pepton was still present.

Free fatty acids (as the result of a fat splitting ferment or of the similar action of the pepsinhydrochloric acid) could not be found.

Gräbner notes that some of these results differ markedly from those obtained by Leo¹⁵ a couple of years ago. Leo found that gastric digestion ended in one and one-half hours in the first mouths of life, but as he did not wash out the stomachs as Van Puteren did, small quantities of material might escape attention. Leo agrees that the acidity is in general much less than in the adult, but gives no definite figures and usually finds lactic acid in the later periods of the digestive process. Leo also found the milk-curdling ferment always, even in the stomachs of the new-born, and his estimate of the antifermentative powers of the sucking's stomach is much higher than that of Van Puteren. It is not always clear how these discrepancies are to be explained.

THE CURDLING OF MILK AND BLOOD.

Some additional light seems to be thrown upon the coagulation processes in milk and blood by the work of Arthus and Pages.¹⁶ These authors point out that we must carefully distinguish three different things in the behavior of casein: precipitation, as by an acid (since it may be dissolved again by alkalies); coagulation, by heat in the presence of an acid; and finally, "casification." The action of the "labferment"

¹⁵ H. Leo: Über den Prozess des normalen u. krankhaften Magen u. d. therapeutischen Erfolge der Magenausplättung im Säuglingsalter. Berl. klin. Wochenschr., 1888.

¹⁶ Arthus and Pages: (1) Recherches sur l'action du lait et la coagulation du lait dans l'estomac et ailleurs—Archives de physiologie, xxii, 331; (2) Sur le labferment de la digestion du lait—ibid., 356;

(3) Nouvelle théorie chimique de la coagulation du sang—ibid., 739.

(rennet)¹⁷ is declared to be that of preparing the casein for curdling and not the curdling itself. The "caseification" has then two steps: (1) a transformation of the casein by splitting it into at least two substances, "hémicaséinalbumose" (the albuminous substance of milk serum) and "caséogene," the forerunner of caseum¹⁸; (2) the combination of "caséogene" with salts of alkaline earths to form various compounds of which the type is the ordinary "caséum." This process takes place in the stomach as well as in the test-tube. The function of the "curdling ferment" is, therefore, according to this view, digestive, and to be classed with that of pepsine and trypsin. The real curdling depends upon the salts of calcium (particularly the phosphate of calcium).

These results led to the study of the coagulation of the blood and to the demonstration of its dependence upon calcium salts. The conclusions may be given nearly in the words of the original.

(1) The coagulation of the blood may be absolutely prevented by the addition of oxalates, fluorides, or soaps. Blood to which the oxalate of potash is added as to make a 0.1% solution [that is, 1.0 oxalate to 1000 blood] will not clot even when putrefaction comes on. The oxalate may be added as a solid, or more conveniently, in solution, but any less proportion than 0.1% will merely delay the coagulation. The oxalate of sodium or ammonium or the fluorides of the alkalies may be used, or even soap solutions.

(2) As this procedure may arrest an impending coagulation or one already begun, it is inferred that the salts do not prevent the formation of the ferment.

(3) This action is due to a decalcification. "Oxalated" blood which is permanently incoagulable will coagulate readily when the calcium salts are replaced, the clot forming in six to eight minutes upon the addition of a 1.0% solution of calcium chloride in the proportion of one-tenth of the volume of the oxalated blood. The action of the oxalates does not resemble that of neutral salts, for no mere dilution will clot oxalated blood as it does salted blood. In other words, the presence of soluble calcium compounds is essential to coagulation, and anything that removes them hinders the coagulation. The calcium salts may be replaced by those of strontium but not by salts of barium or magnesium.

(4) Fibrin is a calcium compound. The amount of fibrin obtained by adding the calcium salts to oxalated blood is sensibly proportional to the amount of the salts in solution.

(5) It is not a transformation of the fibrinogen into a substance capable of uniting with calcium salts to form an insoluble compound, for the coagulation is not instantaneous. The ordinary fibrinogen of the pure or of the salted plasma may be obtained by applying common methods to the decalcified blood.

In this connection it is worth while to note the results reached by Söldner after examining the relation of the salts to the casein:

Söldner starts from the observation that the basis of

the ash of milk cannot be neutralized by the acids present as the amphoteric reaction of the milk requires. He shows that 25% of the phosphoric acid comes from the phosphorus of the casein (or its nuclein), and is preformed in the milk. Casein behaves like an acid inasmuch as it may form salt-like combinations with alkalies, two of which Söldner was able to distinguish as neutral or basic calcium compounds (with 1.55 and 2.36% CaO respectively).¹⁹ The neutral compound is probably present in the milk.

The existence of various organic acids in the milk is also very probable. Henckel has recently obtained one gramme citric acid from a litre.

Only 52% of the calcium oxide in combination with acids appears in the filtrate obtained with porcelain under pressure. The rest, then, appears to be suspended in the milk as insoluble di- or tri-calcium phosphate. The calcium salts play an important part in boiling and in the curdling process. Heated milk shows a more marked increase in alkaline reaction which loses itself on cooling, but all feebly alkaline liquids do the same. It is not true that boiled milk cannot be curdled with rennet. The process is much slower because a portion of the essential calcium salts has been changed by heat to insoluble tricalcium phosphate. The addition of alkali has a similar action. Introducing CO₂ or any acid to make the phosphate soluble brings back the curdability. In the same sense the addition of calcic chloride hastens the curdling.

Reports of Societies.

THE NEW YORK ACADEMY OF MEDICINE. SECTION ON GENERAL MEDICINE.

STATED Meeting, February 16, 1892, A. A. SMITH, M.D., Chairman.

DR. W. W. VALZAH read a paper on

THE CAUSATION AND TREATMENT OF CHRONIC DIARRHEA.

Diarrhea, he said, whether conservative or not, was always exhausting, if maintained for any considerable time. It should always be the aim of the physician to try to find out the cause of the trouble; although it was not always possible to connect chronic diarrhea with a distinct lesion of the intestinal tract, nor were its relations to functional disturbances as yet fully determined.

The most marked characteristic of the stools was their fluidity; but they were also altered in chemical composition and other qualities. It was important to make a careful study of the stools, and it was to be borne in mind that these generally varied from day to day, and often in accordance with the character of the food taken. In many cases more or less undigested food would be found in them. Chronic diarrhea being for the most part a conservative process, except in the rare variety which was purely nervous, was not infrequently found in connection with advanced organic disease of the heart, lungs, kidneys and other organs. From a therapeutic view it was very important to get at the starting-point of the trouble. Commonly in the class of cases most frequently met with, there were

¹⁷ Apparently on account of the change in the view taken of its action, the term "laborient" is retained in these articles, although Paget had proposed the name "peixine" in his thesis [Keicherthes sur la peixine, 1885]. Peixine would be an admirable name for a curdling ferment, and one which might be used to form hemopeixine (or hemopeixine), or the fibrinogen of the pure plasma, but I have been told by Professor Goodwin, who kindly sent me his thesis, that he had been remonstrating with me that Aristotle used οὐράνιον in connection with the coagulation of milk and blood. I suggested the use of the word to Professor Foster, in ignorance of Paget's thesis, but "rennin" had unfortunately already been adopted.

¹⁸ Söldner: Die Salze der Milch u. ihre Beziehung zu dem Verhalten des Caseins. Dissertation, Erlangen. Noted from Escherich's Summary in Jahrbuch f. Kinderkr., xxxi, 173.

some defects in the three great processes of secretion, elimination, and metabolism, and an important connecting link was auto-infection. The quantity of toxines might be abnormally increased. Some of the toxines contracted, others dilated the blood-vessels; and some paralysed, while others stimulated, the nerves. The prevention and treatment of auto-infection constituted the most important element in the successful management of chronic diarrhoea.

All cases might be roughly divided into two great classes: those in which lesions of the intestines are present, and those in which they are not. In the cases where there was only functional trouble the disease was mild and more or less intermittent, and no evidences of inflammatory action were found in the stools; while chronic enteritis was characterized by more or less constitutional disturbance and by tenderness on pressure at certain points with the appearance of blood, mucus and pus in the stools, if ulceration was present. The lower down the intestinal lesion, the more frequent and painful would be the movements. If bile matters were found in the stools, it pointed to the small intestine as the seat of trouble.

Treatment.—The treatment, in order to be successful, required the most indefatigable perseverance on the part of the physician, and the most hearty co-operation on the part of the patient. The most minute directions were to be given and carefully followed, and, above all, it was requisite that the medical attendant should infuse hope and courage into his patient. Among the essentials were good hygienic surroundings, a carefully regulated life, and proper diet. The most detailed instructions as to clothing, bathing, rest and exercise should be given. Warm clothing was required, and especially over the abdomen. In the beginning a warm plunge or sponge bath was of great service in causing increased elimination of toxine. Absolute rest in bed was necessary in some cases for a considerable time. Later, in the stage of convalescence, moderate exercise was beneficial.

The treatment was to be based on the etiology, and had very little to do with the control of the symptoms by opiates and astringents. Checking a diarrhoea by drugs was only temporizing, and it commonly ended in producing an explosion in the system. Active elimination by all the emunctories was usually called for, and "free drainage" was as important as in surgery. In addition, it was important to improve the condition of the blood in every way possible. In general, therefore, careful alimentation and active elimination were the prime requisites.

In particular, the first thing to do was to cleanse the alimentary canal and keep it clean and sweet. Cholagogues and purgatives were called for, and among the agents to be used were bichloride and biniodide of mercury, calomel, and salicin. Cascara sagrada was the most valuable laxative at our command, and in general those drugs were to be selected which least overtaxed the diseased part. In some cases stomach-washing, not too frequently repeated, and in others copious draughts of hot-water were of great service. The latter had a good effect upon the liver and also counteracted fermentation in the intestine. If there was much mucus the addition of an alkali to the water was called for. Mérck's salicin was the only salicin that he had found to be active, and it was often useful in ten or twenty grain doses. Salol was by far the most efficient duodenal disinfectant. When the large

intestine was at fault bismuth was of service, if given in sufficiently large doses. To assist the stomach dilute hydrochloric acid was sometimes required. It was to be given two or three times within two hours after eating in doses of from five to ten drops.

A diet of animal food was often of the greatest possible service, especially as it was important in many cases that digestion should take place principally in the stomach, in order that the diseased intestine might be given a physiological rest. Milk was not suitable in disorders of the small intestine, and in general, on account of the difficulty of getting it pure and fresh and the rapid changes which it was apt to undergo, it was not as desirable an article of diet as meat. If the trouble were located in the colon or low down in the ileum, however, a milk diet was often advisable. The treatment might be summed up as follows: Prevent auto-infection; cleanse the alimentary canal; secure perfect digestion of the food taken; treat the lesions; treat the sequelæ; control harmful symptoms.

DR. ANDREW H. SMITH called attention to malaria as a cause of chronic diarrhoea. The diarrhoea might possibly be the only evidence of the malarial poison in the system, and would soon disappear after the institution of anti-periodic treatment. He agreed with Dr. Van Valzah that a large number of cases of chronic diarrhoea did much better on an animal than on a farinaceous diet, and that the reason for this was that rest was secured for the intestines by throwing the work of digestion on the stomach. In some cases we had a diarrhoea which was due to imperfect action of the pancreas, and in these the administration of ether appeared to be indicated.

DR. C. E. QUIMBY said that it had taken him a long time to get out of the old way in which he had been brought up of treating these cases with opiates and astringents. He now believed, however, that it was just as necessary to clean out the intestinal canal in chronic diarrhoea as it was in acute diarrhoea due to any source of irritation, like green apples, for instance; and he invariably began his treatment with a cathartic. In the diarrhoea of tuberculosis he believed that it was very important for the relief of the pain so frequently complained of, as well as the looseness of the bowels, that the food should be digested before it reached the diseased glands in the intestine. He had, therefore, adopted the practice of giving large doses of pancreaticin an hour or an hour and a half after eating, and had found it attended with very good results.

DR. V. AGRAMONTE spoke of the liability of milk to undergo putrid fermentation, which often set in long before there was any evidence of lactic fermentation, and said that in warm weather especially, if milk was called for, he thought it was better to use condensed milk, which was not open to the same objection. He also spoke of haemorrhoids as a cause of chronic diarrhoea which ought not to be overlooked.

DISCUSSION ON OPIUM-POISONING, ESPECIALLY FROM THE MEDICO-LEGAL SIDE.

The discussion was opened by DR. ANDREW H. SMITH, who said at the outset that the symptoms were sometimes insufficient for a positive diagnosis. Having mentioned that when larger doses of opium were taken the stage of excitement was usually very brief, he gave a short summary of the ordinary signs of opium narcotism. In speaking of the contraction of the pupils, he said that while this was, as a rule,

perfectly symmetrical, one case was mentioned by Wood in which the pupil of one eye was contracted, while the other was dilated. He believed that too much stress should not be laid upon the contraction of the pupils. Before death the pupils generally became dilated. Then, too, it was well to remember that the atropia now so frequently associated with morphia in hypodermic injections, tended to produce dilation.

The condition of the respiration, he went on to say, was generally regarded as the most certain indication of the effect of opium on the system. While, however, it was undoubtedly true that the slowness of the respiration was, as a rule, an index of the extent of the narcotism, cases ending in death were on record in which the respirations were but little, if any, slower than normal. He then mentioned two such cases, one occurring at St. Luke's Hospital, and the other at Bellevue. On the other hand, he had seen one instance in which one-eighth of a grain of sulphate of morphia reduced the respirations to thirteen per minute.

In speaking of the differential diagnosis he said that the pupils were very rarely equally dilated and that there was apt to be strong pulsation of the carotids. In apoplexy it was not possible to rouse the patient, though reflex movements could be excited; while in opium-poisoning the patient could often be temporarily roused, but reflex movements could not be produced. In apoplexy there were often movements of the arm or the leg on one side (the other side being paralyzed), and this was not the case in opium-poisoning. The symptoms of apoplectic effusion into the pons Varoli were said to be identical with those of opium-poisoning, but it seemed to him difficult to conceive of a lesion situated so exactly in the median line as to produce precisely similar effects on both sides of the body. In compression of the brain there was usually some evidence of external violence. A patient suffering from alcoholism was apt to babble incoherently, which was not the case in opium-poisoning, and the cold douche was usually effective in dissipating to a marked extent, the symptoms of alcoholic intoxication. In many cases of opium-poisoning, the odor of the drug could be detected in the breath and in matters vomited.

In uræmic coma the presence of albumen and casts in the urine would usually establish the true nature of the case. To what extent renal inadequacy might intensify the action of opium was a question of interest. In a case where albumen was found to be present in the urine he had known a dose of McMunn's elixir equal to one-sixth of a grain of sulphate of morphia to produce death in twenty-two hours, notwithstanding the most energetic treatment to save the patient. In another case which he had seen, an ordinary dose of morphia given after a surgical operation was followed by death, and at the autopsy granular kidney was found. In speaking of the matter of idiosyncrasy, he referred again to the case previously mentioned, in which one-eighth of a grain of morphia reduced the respirations to thirteen to the minute, and mentioned another in which a small quantity of morphia absorbed through the skin produced profound narcotism, the respirations falling to the extreme point of five in three minutes. The post-mortem appearances after opium-poisoning were for the most part negative, and would throw but little light unless the presence of the poison could be shown by chemical tests.

DR. VAN VALZAH mentioned a case of tobacco-poisoning he had seen, in which the pupils were contracted in precisely the same manner as by opium.

DR. P. BRYNBERG PORTER spoke of a case of diabetes where a small dose of morphia given hypodermically for the relief of pain had apparently been the exciting cause of fatal coma which was no doubt already impending.

The Chairman related some cases which had occurred in his experience. One was that of a patient whose respirations became reduced to two per minute, but which, like the remarkable case mentioned by Dr. Smith, recovered. Another was that of a man suffering from rheumatic gout who died, notwithstanding the most energetic treatment, from the effects of a dose of one-sixth of a grain of morphia given for the relief of pain. The autopsy revealed a cirrhotic kidney. A third patient whom he had seen when an inmate of Bellevue Hospital, some twenty years ago, died with all the evidences of opium-poisoning, and at the autopsy a clot was found in the pons, situated directly in the centre, and nearly half an inch in length. It was the only case of the kind that he had ever met with, and he regretted that he had not preserved the notes of it. He remembered, however, that the respiration was of a stertorous character. In conclusion, he called attention to two points. The first was, that in doubtful cases it was highly desirable that the urine should be examined for the presence of opium, as it afforded a valuable aid to diagnosis. The second was in regard to contraction of the pupils. He had seen this present in cases of alcoholism when there was pachymeningitis on both sides and extending pretty well forward.

THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

Thirty-first Annual Meeting, January 9, 1892.

DR. T. M. ROTCH reported

CASES OF ATROPINE AND OPIUM POISONING IN EARLY LIFE.¹

DR. S. E. WYMAN said: I have but little to add to Dr. Rotch's interesting account of the case just reported, except to state what part was taken by me after Dr. Rotch was called away.

Certainly, when first seen by me, at 10 a. m., she was in a pitiable state; being dragged about the piazza between two attendants, one of whom supported her on either side; her head was hanging on one side, her eyes closed, and her legs dangling in her forced journey. When taken into the lap of the nurse brought by Dr. Rotch, her head fell immediately upon the nurse's shoulder, and she fell fast asleep, requiring constant efforts to keep her awake. In an interval of consciousness, she begged to be allowed to go to bed. Her pupils were contracted to an almost pin-hole size; her pulse rapid; her respirations not noteworthy; her skin pallid and cool.

She vomited several times after 10 a. m., coffee and water containing the belladonna mixed by Dr. Rotch. At 10.20 she was put into a mustard pack, vomiting at the smell of the mustard. At 10.30, I injected subcutaneously atropine sulphat., gr. $\frac{1}{10}$. It was truly remarkable to see the effect which followed this

¹ See page 231 of the Journal.

within forty-five minutes. Whereas, previously, it was necessary to speak to her every thirty to forty seconds to prevent her from sleeping, she then began to sit up and notice people, who were standing on the street before the window where she was held by the nurse. She did not, however, remain awake voluntarily for any length of time so that I repeated the same injection at 11.20 A. M.

At 12.10 P. M., she was much improved, sat up, asked to be dressed (as she had been previously in a blanket) directed what gown she preferred, etc. The effects of the atropia were marked in the efflorescence of the skin, the dryness of the mouth and dilatation of the pupils. When dressed, she desired to walk out on the piazza, and did so.

I stayed with her until 1.30 P. M., when she was quietly resting on the sofa, but perfectly conscious and wakeful although weary.

The cases which occurred in my own practice were in very young infants, and, in two instances, interesting from the fact that the source of the poisoning was a famous patent cough-balsam sold and advertised extensively.

CASE I. Florence C., aged twenty-three days, had been coughing for several days, and had been treated by her mother. I was hurriedly summoned at 3 P. M. on November 11, 1891, with the message that the baby was dying and could not be aroused by anything which the mother could do. I saw her at 3.15 P. M., when I found the infant plainly under the extreme effects of opium. She was cyanotic, cold, almost pulseless, and drawing a feeble breath only at long intervals. The pupils were mere pin-holes, the thumbs clinched tightly in the palms of the hands.

I learned from the mother that, as the child had a bad cough, she had given her, at 8 A. M., just after nursing, some Adamson's Cough Balsam, just how much, it was difficult to learn, but probably between five and ten drops; that the child went to sleep soon after, and the mother thought nothing of it until 2 P. M., when she tried to arouse her without success. After working some time, she sent for medical help.

At 3.20 P. M. she was put into a hot mustard pack. Her color improved some, but otherwise her condition remained the same. There was delay in getting the solution of atropia, so that it was 3.40 before I gave her gr. $\frac{1}{15}$ by subcutaneous injection; and this was repeated at 4 P. M. She began to improve, the pupils dilating and the skin becoming bright scarlet. It was not until 9 P. M. that she was sufficiently awake to the nurse. From this time on her recovery was rapid.

In the same room was a child two years and ten months old, who had been similarly treated with Adamson's Balsam, who was so drowsy that he could keep his eyes open for a few seconds at a time only. He was, however, so much less under the influence of the opium that no treatment was given him.

CASE II. Frances W., aged five weeks. I was called to see her November 21st at 7.30 P. M., the message being that "the child could not be roused, and was dying." This infant had been seen by me some days previously, and a prescription of liquor ammon. acetatis, syrup ipecac, syrup tolu and water ordered.

When seen she was very much in the same condition as the first case. The skin was purple and cold; the pupils contracted to the extreme degree; almost no efforts at respiration; and at each attempt the noise

of mucus in the throat; scarcely any pulse to be detected at the wrist; and the thumbs tightly clinched in the palms of the hands. She was plainly under the marked influence of opium, and apparently about to die.

At a loss to know where any opium could have been obtained, I learned that the mother might have given the child by mistake half a teaspoonful of a prescription, written by me in March, 1889, for a child seven years old, which contained, as I learned afterwards from the druggist, tr. ipecac Co., twenty drops to two fluids ounces.

I gave the child some hot whiskey and water, put her into a hot mustard pack, and at 7.45 P. M. gave, by subcutaneous injection, atropin sulph., gr. $\frac{1}{15}$; and at 8 P. M., atropin sulph., gr. $\frac{1}{15}$, by subcutaneous injection. She began to improve, so that at 8.30 P. M., by slapping, she was made to cry, but would lapse off to sleep if left alone. She began to breathe better, and coughed some. The pupils dilated, and the skin became red but not scarlet. The thumbs, however, remained in the same position, and there was a lateral deviation of both eyes, now to the right and again to the left, as late as 9.30 P. M.

Her recovery after this was uneventful.

DR. A. D. SINCLAIR had seen no cases in children, but remembered very well one marked case in an adult, of atropia poisoning, caused by a large dose given subcutaneously in the days when subcutaneous syringes were first heard of. Having no electric battery at hand, he had restored to the use of a cold douche, with good results.

DR. J. G. BLAKE said we all know that infants and rabbits will take large doses of belladonna with very little physiological effect. Among adults, too, there is a great difference in the susceptibility to this poison. Some years ago he was called to see a young man who was suddenly taken violently ill with all the symptoms of belladonna poisoning, including the rash, and dry throat. Vanilla ice-cream was found to be the cause. He was told by Dr. B. F. Davenport that a spurious bean sometimes used in making vanilla extract produced symptoms of belladonna poisoning. His patient recovered.

DR. E. J. FORSTER said he had given, in a severe case of opium-poisoning, one-half a grain of atropia, followed in fifteen minutes by one-quarter of a grain more, with recovery. Stillé says that one-quarter of a grain of atropia has caused alarming symptoms, but that less than one grain has never been fatal.

DR. R. L. HODGDON had also injected half a grain of atropia in opium-poisoning, with ultimate recovery.

DR. T. M. KOTCH said that the cases reported to-night teach us that it is our duty to warn people not to keep medicines too long, as they evaporate and become much stronger.

DR. S. E. WYMAN referred to a case where suppositories had been used, presumably containing opium, where the infant was made very drowsy.

DR. C. W. TOWNSEND said he had once written for six suppositories containing a small dose of both atropia and morphia, one to be given to a child each night for incontinence of urine. The apothecary had put the whole quantity into one suppository, and the child received a dose of each drug six times as large as was intended. Either one of the drugs alone might have produced serious results, but the two antagonized each other; and the result was simply drowsiness the next morning, and also a cure of the incontinence. The

apothecary admitted that the error was his, and that the prescription was properly written.

DR. EDWARD REYNOLDS gave a *résumé* of the paper read by him last time, entitled
CASES OF LABOR COMPLICATED BY PROLAPSED OVARIAN TUMORS,²

the discussion of which was deferred to this meeting.

DR. F. B. HARRINGTON said he thought there would be no objection to tapping the cyst if one was sure of his diagnosis. He should be tempted to insert a fine needle first for diagnostic purposes.

DR. G. HAVEN said that the case at the Lying-in Hospital was interesting from the point of view of diagnosis. It does not seem possible that an ovarian tumor could disappear in such a short time.

DR. W. L. RICHARDSON had not seen a case of this sort, but he would not object to puncturing the cyst with trochar, in order that delivery might take place.

DR. EDWARD REYNOLDS replied that he should fear peritonitis from the escape of a harmful fluid into the peritoneal space between the tumor and the vagina. He thought that it might be forced out around the trochar; and at all events some of the residual fluid would be pressed out after the removal of the trochar. The puncture in the vagina he should consider dangerous in the presence of the lochial discharge. The puncture of large pus-tubes would certainly be serious or fatal.

DR. A. WORCESTER said he had had no experience in these cases; but it seemed to him that the only thing to be done would be to tap, thus removing the obstruction, and if need be do an immediate laparotomy after the delivery. Laparotomy before delivery he believed would be almost impossible.

DR. G. HAVEN would agree with Dr. Worcester.

DR. F. B. HARRINGTON said the existence of prolapsed pus-tubes as a bar to delivery would probably never occur, as their existence would also be a bar to conception. And therefore he did not believe that laparotomy, to prevent peritonitis after tapping, would be necessary.

DR. E. REYNOLDS remarked that he was glad to hear the various opinions of the Society, having introduced the remarks on treatment for that purpose.

DR. F. H. DAVENPORT said that it would certainly be very rare that a non-adherent ovarian cyst should come down in advance of the head. A dermoid cyst or a fibroid tumor might do so, or a cyst bound down with adhesions. If these were present tapping could do no harm. The chocolate-brown contents of some cysts, or the contents of dermoid cysts are not septic and would do no harm.

DR. WYMAN referred to a case where there was a large cyst of the vaginal wall interfering with the examination of the os in labor. He tapped, and drew off several ounces of fluid.

DR. DAVENPORT had seen cysts within close proximity of the cervix on the anterior vaginal wall.

DR. J. G. BLAKE should certainly tap, if one of these cases should occur in his practice.

In reply to a question in the House of Lords the Prime Minister has declined to assent to issue a Royal Commission to inquire into the London fogs, but has intimated his willingness to support the appointment of a Committee of the House.

Recent Literature.

Treatise on Gynecology, Medical and Surgical. By S. POZZI, M.D. Translated from the French edition under the supervision of, and with additions by BROOKS H. WELLS, M.D. Vol. I. New York: William Wood & Co. 1891.

Dr. Wells deserves the hearty thanks of the profession for giving us this valuable work in English, and is to be congratulated on the admirable manner in which the translation has been made. Pozzi's work is the latest comprehensive exponent of the French school of gynecology, and it demonstrates the fact that in that country the leading workers in this department are fully abreast of the times. We have here a book of which no country need be ashamed. In comprehensiveness of treatment, in catholicity of opinion, and in clearness of expression, it ranks with the best works on the subject.

It would be a pleasure to review it in detail, but it would be impossible to do justice to it in a short article. The order in which the subjects are treated suggests that clinical lectures formed the basis of the book, and the author says that such is the fact. Anatomy is left out, and wisely, as it seems to us. The first four chapters deal with antisepsis (a very thorough and valuable *résumé* of the subject) anesthesia, wound closure and control of hemorrhage and gynaecological examinations, all subjects of general interest. Then follow three chapters on metritis, which cover more ground than is usual under that title, since they include endometritis, endocervicitis, affections of the cervix, erosions and lacerations, as well as metritis proper. A most exhaustive treatment of the subject of fibroma of the uterus, occupies six chapters, and the various forms of medical and surgical methods employed for their relief are very fully described. More than the usual space is given to methods of vaginal enucleation. The following three chapters deal with carcinoma of the uterus, followed by four on displacement of the uterus, one on deformities of the cervix, and one on disorders of menstruation. In all, we have a book of nearly six hundred pages, which is issued in a very attractive form by the publishers. The notes by the translator add distinctly to its value, and not the least useful feature is the bibliographical notes which have been grouped together at the end of the various chapters.

A large number of engravings and six colored plates add to the attractiveness of the book. Taking it all in all it is one of the best books we have seen for a long time and no specialist can afford to be without it.

The Physical Diagnosis of the Diseases of the Heart and Lungs, and Thoracic Aneurism. By D. M. CAMMANN, B.A., Oxon., M.D. New York and London: G. P. Putnam's Sons. 1891.

The present book is one of a number which have recently been published on the subject of auscultation and percussion, and though well written, contains nothing to especially distinguish it above the others. The author is to be commended for introducing a short chapter on acoustics, but we doubt if American physicians will unreservedly agree that "the pleura is the frequent if not the only seat of crepitant and subcrepitant râles, as well as a sharer with the bronchi in the production of coarse and gurgling râles."

SPECIFIC GRAVITY OF THE BLOOD.

THE specific gravity of the blood has recently been studied again by Peiper,¹ using the method of Schmaltz,² by which a small quantity of blood is weighed in a "capillary pyknometer." This method proved satisfactory, giving exact results from which the following conclusions were derived:

(1) The specific gravity of the blood of healthy human beings varies but slightly—1045 to 1046—with an average which is somewhat higher for men (1055) than for women (1053) or children (boys, 1052, girls, 1050). Landois has given 1055 as an average with a range from 1045 to 1075, while Jones, using a method like that of Roy, noted a range from 1035 to 1068.

(2) Pathologically, the variations may be relatively considerable (1025 to 1068). The specific gravity is lowered in nephritis, chlorosis and anæmia, as well as in diseases producing marasmus (for example, *phthisis pulmonum* and *carcinoma ventriculi*), but raised in febrile diseases and in conditions leading to marked cyanosis.

Schmaltz³ has also published some results obtained by his methods which may be given here nearly in his own words. Normally, the specific gravity of human blood varies within narrow limits, but is, as a rule, considerably lowered in anæmic conditions, most of all in chlorosis and in blood diseases properly so called. The specific gravity seems to depend chiefly upon the amount of haemoglobin, and to have only a very limited dependence upon the number of red corpuscles. As anæmic conditions improve the specific gravity of the blood is raised and may apparently serve as a good criterion of the stages of the disease. If the circulation in the extremities becomes sluggish the specific gravity of the blood is not infrequently raised, and

may be found to be normal despite existing anæmia (as in heart and lung troubles).

In Roy's⁴ method for examining the specific gravity of the blood, drops are brought into standard mixtures of glycerine and water until one is found in which the blood just floats, neither sinking nor rising. Jones⁵ modified this procedure slightly and found the method very convenient in a long series of observations.

Quite lately Jones⁶ has published a long article concerning his investigations, and some conclusions which he considers that they permit, despite an acknowledged incompleteness. The method is still substantially that of Roy, the standard solutions being mixtures of glycerine and water with the addition of sodium silico-fluoride, which Jones considers an efficient antiseptic in neutral or slightly acid solutions. The solutions are prepared with great care, using very accurate hydrometers and keeping "all the apparatus at exactly 60° F.," but it is maintained that the ordinary variations of temperature have no effect upon the measurements since the small column of blood in the fine pipette rapidly assumes the temperature of the liquid in which it is placed. A large number of such solutions are kept on hand for specific gravities ranging from 1027 to 1075. With a sufficient number it is asserted that results may be reached which are accurate to within "one-third of a degree," and Jones considers the limit of possible error in his own observations to be "not more than half a degree." The method has the advantage of great rapidity, but the details should be studied in the original.

It is difficult to condense the results which Jones presents, and still more difficult to be certain that they are all correct. Tables are given in chart form detailing the observations on 495 males and 662 females, all in good health. These charts show unquestionably that the range of the specific gravity of the blood is very great in the first year for both sexes, and then seems to lessen for several years becoming great again in women of thirteen to twenty-five years (a normal inclination to anæmia), and broadening out once more for both sexes in old age. Jones's summary of the points shown in the chart is as follows (page 344): "The specific gravity is generally lower in women than in men, but it is about the same in both sexes before the fifteenth year: and is higher in old women than in old men. In males, the specific gravity is about 1068 at birth—falls during the first year and subsequent two years, being about 1050 in the third year: thence it rises till about seventeen years of age, when it is about 1058. It remains as high during middle life, and falls slightly in old age. In females, the specific gravity is about 1066 at birth: it falls in infancy, as it does in males, to about 1049 in the third year. Thence it rises till the fourteenth year, when it

⁵ E. Lloyd Jones: On the variations of the specific gravity of the blood in health. *Journal of Physiology*, viii, 1.

⁶ E. Lloyd Jones: Further observations on the specific gravity of the blood in health and disease. *Journal of Physiology*, 1891, xii, 259.

is 1055.5. Between seventeen and forty-five years of age it is lower than in the female at fourteen, being about three degrees lower than in the male. The widest range occurs during the first year because the specific gravity is very high at birth and falls to a very low point during the first six months." The observations are apparently numerous enough for persons of ten to thirty-five years of age, but are almost too few for the later years of life and quite insufficient for the earliest. To generalize from nine boys and five girls, whose ages are tabulated as ranging from birth to one year, or from eight boys and three girls noted for the next year is, to put it mildly, exceedingly unsafe. The specific gravity of the blood at that age *may* be exactly what Jones states it to be, but his chart does not demonstrate it (at least not for males), and in view of the peculiar nature of growth during that time very many more memoranda are needed.

Jones finds a resemblance between his curves and those of Leichtenstern for haemoglobin and infers that the variations of this substance are closely related to those of the specific gravity.

The specific gravity of a drop of blood varies somewhat according to the locality, being lower where the blood flows readily (fingers and toes) than where it is obtained with less ease (nape of neck, arms, legs): it is also lowered by active congestion but raised by passive congestion (ligature). Suggestions of racial peculiarities are found in the fact that the specific gravity is rather more in persons with light eyes than in those with dark eyes. Some other variations according to "temperament" and "type" are noted in the original. The specific gravity is also further affected by food and exercise, food usually lowering it in an hour or two, but alcohol raises it, while the action of hot liquids is not uniform; exercise of a gentle character depresses, but prolonged or violent exercise elevates this quality of the blood, and regular exercise (as in the boating men) was found to be associated with a permanently high specific gravity. Sleep generally causes it to rise but the effect is not as constant as the author had supposed from his earlier observations.

The blood of birds appears to be heavier (1059 to 1075), and that of the frog lighter (1034 to 1053), than in man. About half of the article before us is taken up with the measurements made in disease, but in view of the fact that variations of three to ten degrees in each individual are common (page 313), and also in view of the conclusion (No. 6, page 343) that "the specific gravity varies considerably in different persons, so much so that a specific gravity which is normal for one may be a sign of disease in another," and furthermore in view of the circumstance that no definite statement is made as to the number of measurements, these measurements must be read to be appreciated.

If any conclusions are to be drawn from the specific gravity of the blood in pathological conditions, some very different method of collecting the blood will prob-

ably have to be employed, although this method of examining what is collected appears to be easy and trustworthy.

ETIOLOGY AND NATURE OF TYPHUS FEVER.

FORTUNATELY it cannot yet be said that typhus is endemic in this country, though how long we shall be free from it with our present reckless admission of a debased immigration is a question which at best admits only of a doubtful answer. It is still both endemic and epidemic in many parts of Europe, though some of its former favorite haunts, as Glasgow, have been purged of its presence by intelligent sanitary measures. This epidemicity and the conditions of diffusion are well expressed in the terms so frequently applied to this disease: *ship fever, famine fever, army fever, prison fever*, etc.; that is, where great numbers of human beings have been massed together under unhealthy hygienic conditions, typhus has ever prevailed with great intensity. It has in past ages, in innumerable instances, been the scourge of armies. In the late war between the Russians and Turks, fifty thousand men are said to have fallen victims to this disease (Thoinot).

It is in an eminent degree both infectious and contagious. Neither sex nor age has any marked influence. Misery, famine and filth are the most potent predisposing conditions. Marchison's statistics give ninety-six per cent. of cases among the inmates of workhouses and the denizens of slums. The worst epidemics in Ireland have coincided with years of famine. The famine districts of Russia are this present year a hot-bed of typhus. The predisposing influence of over-crowding and want of ventilation is everywhere acknowledged. The contagious nature of the disease is attested by the success of prophylactic measures, and in particular, of isolation of the sick. It is undisputed that typhus is transmitted from person to person, by direct contact. Another fact, well established, is its transmission by clothing, by infected ships, houses, furniture, etc. It resembles in this respect the eruptive fevers, small-pox, scarlatina, measles. According to Marchison, typhus is most communicable by sick persons from the end of the first week till convalescence.

Numerous researches have been undertaken to discover the germ of typhus fever. Those most worthy of mention are the investigations of Hlava, and those of Thoinot, undertaken in collaboration with Calmette. Hlava, when studying an epidemic of typhus at Prague in 1888, referred the cause to a strepto-bacillus which he has figured and described. But this strepto-bacillus is by no means constant, and Cornil and Babes think it only a secondary and unimportant micro-organism. Thoinot and Calmette find numerous microbes, and frequently, but not always, the strepto-bacillus of Hlava. They find constantly in the blood of typhus patients "an interesting organism," which they regard as *sui generis*; unfortunately it has not been cultivated.

The blood of typhus patients is, they say, not cultivable or inoculable in small animals, as rats, guinea-pigs, hares, etc. It is evident then that new researches are needed before the causal agent can be said to be identified.

Empirically, it has been determined that the air is not a good vehicle for the propagation and transmission of the germ, whose power of extension does not exceed a very limited zone around the sick person. Without direct contact with the patient, or with objects that harbor the germ, as clothing, there can be no contracting of typhus (Thoinot). The facts that substantiate this proposition are numerous.

According to most recent authorities, the rôle of potable water in the propagation of typhus fever is not great, at least as compared with the relation of drinking-water to typhoid fever in the transmission of that disease. Thoinot, whose recent memoir we have studied in this connection,¹ thinks it doubtful whether typhus be inoculable by the digestive tube. He believes that the germ has a special affinity for the secretions of the skin, fixing itself to them and being thereby transmitted in the form of exhalations, or communicated to susceptible persons by touch. It is not definitely known how far the lungs are a medium for the inoculation of the infectious agent.

Thoinot finishes his chapter of etiology with these conclusions :

(1) Typhus is, in all probability, the function of a figured germ, whether that described by Hlava, the one studied by myself, or some other micro-organism.

(2) Typhus is endemic in certain countries, nor do we know the reasons of this endemicity; whether or not it may be due to the cultivation of the germ in the soil, to the qualities of the races which perpetrate the existence of the germ by slow and successive transmissions, etc. We are very ignorant on these points.

(3) Typhus becomes epidemic in certain cases and spreads far from its starting place, or invades dense agglomerations of people. The adjuvant conditions of the diffusion are overcrowding the general condition, and physiological depravement (*misère physiologique*) a personal condition, which may, moreover be generalized to a collection of individuals, as in cases of tribal or natural destitution and of famine.

(4) Typhus does not always leave behind a focus of endemicity when it invades an army or a country epidemically, in this respect resembling cholera.

(5) The transmission of typhus is effected by direct contact with the patient, or by contact with objects which are charged with the specific germ from intimate contact with the patient.

(6) The channels of inoculation of the disease, as also the channels by which the germ is expelled from the sick organism, are unknown to us. It is probable that the products of cutaneous excretion play a principal rôle.

(7) The air does not appear to be a vehicle of contagion, and the same may be said of water.

¹ *Typhus Exanthematique*, Traité de Médecine, February, 1892.

THE APPROPRIATION FOR THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE ENDANGERED.

The Army Appropriation Bill lately reported by the Military Committee to the House of Representatives cuts down the usual annual appropriation for the Library of the Surgeon-General's Office, United States Army, one-half; that is, this moderate appropriation is reduced from ten thousand to five thousand dollars. This is a penny-wise, pound-foolish piece of work. If this library were a river or a harbor, what a pitiful sum ten thousand dollars would seem to some members of Congress!

Although it is only a library, which for some unknown motive the Military Committee seeks to cripple, we desire to assure Congressmen that they will find that it has warm champions in the members of the medical profession all over the country, who know what this library has become and the services it has rendered and may render to humanity — meaning thereby, the average voter.

If this item is not restored, either in the House or the Senate, the result must be that the formation of a complete medical library at Washington, which has progressed so successfully for the last ten years, must be stopped.

We most vigorously protest against such an unwise and short-sighted attempt at economical (!) legislation.

MEDICAL NOTES.

DR. KARL VIRCHOW STRICK. — We have received a personal letter from Dr. S. Guttmann, editor of the *Deutsche medicinische Wochenschrift*, asking us to call attention to the shortcomings of a certain Dr. Karl Virchow Strick, who has lately been advertising in the daily press of Cincinnati. The particulars given are exactly those which we published last week on page 224, under the title of "A Warning from Virchow."

MORTALITY OF THE STATE OF NEW YORK IN JANUARY. — According to the report of the New York State Board of Health the mortality of January was greater than that of any month previously recorded, except that of April, 1891, which it nearly equals: it arose from a daily average of 291 deaths in November, of 362 in December to one of 434, exceeding the daily average of January, 1891, by 126 deaths, and that of the entire year 1891 by about 100 deaths. The increase is due to epidemic influenza, what may be termed the third outbreak, which reached its height during this month. Compared with January, 1890, and April, 1891, the two months of the height of previous epidemics, the mortality in early life is less, while that of old age seems to be much greater; from acute respiratory diseases, and also from consumption, the number of deaths is considerably less than in either of the other months. Deaths attributed to diseases of the digestive and circulatory systems are increased; compared with previous outbreaks, this one

has appeared to fall especially upon the aged, the number of deaths of old people being double that of the average for January, and next to that upon diseases of the digestive and circulatory organs.

TO INVESTIGATE THE SUBJECT OF IMMIGRATION.

—The National Senate and House Committees on Immigration, have gone to New York and have begun to take evidence as to the character of the present immigration, with a view to formulating a policy which will exclude at least the more undesirable of the enormous number of foreigners who annually come to this country.

AN EPIDEMIC OF INTESTINAL DISTURBANCE IN VIENNA. — Immediately after the recent epidemic of influenza began to decline in Vienna, there appeared a wide-spread epidemic, characterized by fever, acute colic and dysentery, the dejections often containing blood. At first it was attributed to the drinking-water, but this has been analyzed and found to be of normal purity. A difference of opinion exists as to its having any connection with the epidemic of influenza, and time will be necessary before its etiology can be decided.

BOSTON AND NEW ENGLAND.

DEATHS IN BOSTON FOR THE WEEK. — The total number of deaths reported in Boston during the past week was 196 as against 201 the corresponding week last year, making the death-rate for the week 22.2. This is the first week for three months in which the death-rate has not been higher than it was a year ago. The deaths from consumption were 24, pneumonia 32, bronchitis 14; persons over sixty years of age 40. There were 89 cases of scarlet fever reported, with eight deaths.

A COMMISSION TO INVESTIGATE THE PUBLIC INSTITUTIONS OF BOSTON. — The Mayor of Boston has appointed a commission to inspect the public institutions of the city, to examine their condition and present management and to report thereon in writing, together with such recommendations as may seem to them desirable. This commission consists of Mr. Frank Morison, Mr. Thomas P. Ring, Dr. Charles P. Putnam, Dr. Morton Prince, Mrs. William McCarthy, and Miss Annette P. Rogers. The commission has already organized and has made the following announcement: "The duties of the committee are to investigate the system under which the public institutions are conducted, with a view to ascertaining its efficiency or inefficiency, and also to inspect the institutions themselves; to report upon their condition, method of management and needs, with a view to recommending any change in the law, the ordinances, the buildings or the management which in their opinion would be proper or desirable." The institutions are as follows: The almshouses at Charlestown, Long Island and Rainsford Island; the Marcella-Street Home for Neglected Children; the House of Industry, House of Reformation and Truant School on Deer Island; the Lunatic Hospital at South Boston: the buildings at Austin

Farm; and the County House of Correction at South Boston. Communications and suggestions for investigation, as well as recommendations, may be sent to Frank Morison, 60 Congress Street. All such communications must be signed and contain the address of the writer."

COMMITTEE HEARINGS OF THE MASSACHUSETTS LEGISLATURE. — The Committee on Public Health have reported to the next legislature the subject of establishing free warm baths in cities. The same committee reported it inexpedient to legislate on the order that no stables in cities shall be within 150 feet of dwellings. The Committee on Public Charitable Institutions recommended that the petitioners for an appropriation for the Boston Emergency Hospital have leave to withdraw.

MASSACHUSETTS EYE AND EAR INFIRMARY. — The annual report shows that during the past year 11,926 new eye patients and 4,578 new ear patients were treated at the infirmary, an increase of 1,215 over 1890. The number of house patients was 853. The new building for the ear department was completed, and has been occupied since the first of August. The old building is now used entirely for the eye department. A plan and description of the new aural building is given in the report. It was made by remodeling the two houses on Charles Street, next adjoining the infirmary, but separated from it by a passage-way. Except for a bridge connecting the two buildings, the eye and the ear departments are now separate. The ground floor of the new building is devoted to out-patients, above this are three floors containing wards, operating-room and other necessary rooms. The present building is, probably, the most complete hospital especially devoted to diseases of the ear in this country.

TRICHINOSIS. — An epidemic of trichinosis is reported in the town of Coleraine in Franklin County, Mass., in which about thirty persons have been taken ill and two deaths have occurred. These persons were taken ill about February 1st, and their illness is probably due, as usual, to the eating of raw or imperfectly cooked pork. The persons affected are mostly Austrians, Bavarians, and French Canadians, operatives in a mill in Coleraine. With one exception, all the persons attacked are convalescing. The symptoms were general fever, swelling of the face, eyelids and extremities. Perspiration, severe pain in all parts of the body, muscles sore. Contraction of the flexors of legs and arms. This is the most serious outbreak of trichinosis ever reported in the State, and these are the first deaths from this cause since 1870.

TUBERCULOSIS AMONG CATTLE IN MAINE. — The Maine State Veterinary Surgeon, in his annual report, shows that the whole number of cases of tuberculosis reported to the State Cattle Commission during the past year was 117. A great deal is said about tuberculosis in Massachusetts, and the reasons given for quarantine against Massachusetts cattle. Only half as

many cattle were destroyed as in the previous year, owing, the commission believe, principally to restrictions to importations from Massachusetts.

NEW YORK.

DR. LEWIS A. SAYRE. — On the 29th of February, the Rev. W. R. Huntington, Rector of Grace Church, sent to Dr. Lewis A. Sayre, who is one of his parishioners, the following graceful little tribute in verse. On that day the veteran surgeon, who was born in leap year, celebrated his eighteenth birthday, being seventy-two years old.

DEAR DOCTOR SAYRE:

And is it true
That Nature set her clock for you
Some four-and-fifty years too slow?
How clever of her to foreknow
That you would keep yourself so young,
So firm of heart, so sound of lung,
That she would never be detected,
Nor you so much as once suspected
Of being older by a day
Than Leap Year records seem to say!
Eighteen, dear friend, or seventy-two,
Which e'er it be, Good luck to you.

MORTALITY FOR THE WEEK. — During the week ending February 27th, the number of deaths reported in the city was 910, an increase of two over the record of the preceding week, and 58 above the average of the corresponding week for the past five years. This mortality represents an annual death-rate of 27.70 per thousand of the estimated population. The deaths from pneumonia were unusually numerous, 170; against 143 for the week preceding and 125 for the average of the corresponding week in the past five years. There were four deaths from typhus fever and three from small-pox. The deaths from influenza, which amounted to 25 during the week ending February 20th, were 20 in number.

TYPHUS FEVER. — Up to March 4th there had been reported 130 cases of typhus fever, with 7 deaths. As a matter of precaution, all the inmates of a tenement-house on East 12th Street occupied by Russian immigrants, where a large number of the cases have developed, have been removed to quarters on North Brothers' Island; and the sanitary authorities are endeavoring to keep any individual known to have come in contact with a typhus fever patient under close observation. A few of the attendants at the fever hospital on North Brothers' Island are said to have contracted the disease, but none have as yet died of it. The joint committee appointed by the Senate and House of Representatives have arrived from Washington and commenced their investigation of the working of the immigration laws and the introduction of typhus fever by the passengers on the *Massilia*.

The steamer "CALIFORNIA," which arrived on March 3d with 456 steerage passengers on board, was detained at quarantine. During the voyage one of the passengers, a Russian Hebrew, developed small-pox, and one case each of scarlet fever and measles also occurred.

DEATH AFTER THREE DOSES OF BROMIDE OF POTASH. — On the morning of March 3d, a bar-tender, who was locked up the night before in a padded cell in the Hoboken City Prison, while suffering from delirium tremens, died after having been given three doses of bromide of potassium by the police sergeant in charge, no physician having been called in to attend the case. If it is true, as stated afterwards by the captain of the Hoboken police, that it is a common thing to give bromide of potassium to delirium tremens patients brought to the station-house, without special medical advice, and that this is done in police stations all over the country, it is certainly high time that such a practice should be put an end to. In this case the City Physician, Dr. Simon, who was hurriedly sent for when too late, expressed the opinion that the man was dangerously ill when taken to the station-house.

SHORT GENERATIONS. — In taking the new census of the State of New York, a baby, three months old, was discovered in the town of Warrensburg, near Troy, whose mother is not yet fifteen, whose grandmother is thirty-three, and whose great-grandmother is only fifty-four years old.

Miscellany.

NEW BUILDINGS FOR THE JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA.

The Board of Trustees and the Faculty of the Jefferson Medical College have just completed the purchase of two large lots on Broad Street, giving them a frontage of about 300 feet, and a depth of 150 feet, upon which they will proceed to erect at once a handsome hospital, lecture-hall and laboratory building. The estimated cost of the buildings is \$500,000. The hospital will be built not only as a suitable building in which to care for the sick and injured, but also will be provided with a large amphitheatre for clinical lectures. The basement of the hospital will be given over to the various dispensaries, each of which will be provided with large waiting and physicians' rooms as well as rooms for direct teaching of the students. The buildings will be absolutely fireproof and provided with patent sprinklers in case their contents catch fire. By the erection of three commodious buildings, the laboratories where delicate work with the microscope or apparatus is carried on, will be separated from the college hall where didactic lectures are given and so will be free from any jarring produced by the movements of large classes. With the hospital on one side affording clinical facilities and the laboratory on the other side of the college hall for scientific research and training, the college will then be most favorably situated for giving thorough instruction in medicine. Further than this, immediately across the street is the Howard Hospital and on the adjoining corner the Ridgeway Branch of the Philadelphia Free Library, which contains all the scientific works belonging to this wealthy corporation. The new site is even more favorably situated in regard to the centre of the city than the old one at 10th and Sansom Streets. The move has been made necessary by the large number of students

who are now being instructed in this institution and because the Faculty desire to keep the school and hospital in the foremost rank of medical education in this country.

The buildings will be ready for occupancy in the session of 1893-94.

THERAPEUTIC NOTES.

THE TREATMENT OF WOOPING-COUGH.¹—According to the *Bulletin Générale de Thérapeutique*, Galvagno has employed antipyrin combined with resorcin in the following formulae in the treatment of whooping cough in children:

R Distilled water	3 fliss.
Resorcin 	3 gr. xv.
Antipyrin 	55 gr. xv.
Hydrochloric acid	gtt. x.
Syrup	3 t.
Or,	
R Syrup of acacia	3 fliss.
Resorcin 	3 gr. xv.
Antipyrin 	55 gr. xv.
Syrup	3 t.

Sig. Of this, three to five dessertspoons are given each day.

Under this treatment the duration of the disease, according to the author, does not exceed twelve days.

PROPHYLAXIS OF INFLUENZA.—At a recent meeting of the Académie de Médecine, Ollivier said that he had found cod liver oil a prophylactic against influenza, especially in children. Vallin agreed with the speaker, and recommended also careful antisepsis of the mouth, nostrils and throat.

EUPHENON: A SUBSTITUTE FOR IODOFORM.²—Euphenon is a very fine, yellow powder, having neither a disagreeable nor a strong odor. It is one-fifth as heavy as crude iodoform, while the finely-powdered iodoform is two and a half times heavier than euphenon. It is soluble in alcohol, ether, chloroform, benzine, and in fats and oils. Vulpinus finds that anthrax bacilli are generally rendered inert by it. Staphylococci were essentially checked in their development, although perhaps not so much as under the influence of iodoform. Pyocyanes seemed not to be influenced by euphenon. Experiments to determine its toxicity indicate that euphenon is less poisonous than iodoform. It may be used locally in the form of ointment, powder and gauze. It is recommended when rapid and vigorous granulations are to be excited.

Correspondence.

A LOW VALUATION OF A CONSULTANT'S SERVICES.

AN eminent Boston surgeon was called in consultation to a neighboring city. His services consisted of two journeys to that city and back, the aspiration of a tumor, the examination of the contents by an expert pathologist, and the necessary correspondence. The bill rendered the estate, an estate which was said to be ample, and understood to be so at the time of sending the bill, was for \$105. It evoked the following reply from the executor of the patient's will:

"Had I been prostrated to the ground by a thunderbolt from the heavens on a clear summer day, and retained

sufficient consciousness to have realized it, the shock would not have been much greater than that which I received as I looked over the bill you sent me against the estate of Mrs. ——.

"I knew that Dr. —— of this city had consulted a Boston physician, and I have recently paid his bill, amounting to \$190, which I supposed, of course, included the pay for your services (and which I hope may be the case); and even at that I thought the bill was *tremendous*. I feel that Dr. —— did *very wrong* in entailing such an expense, in calling you, as he had previously told me that Mrs. —— could not possibly live *over* three months; and it seemed to me that if any examination was to be made, you would both be amply repaid by whatever information you may have gained thereby; and I cannot refrain from saying that I think the call upon you was wholly unnecessary, and, even if it had been, that your charge for your service was *unjust* and *beyond all reason*; for I don't believe there was ever a human being who possessed sufficient knowledge or ability to make his services worth \$100 a week, while yours was only rendered for a few hours upon a lonely, feeble and emaciated old lady to whom death was not only a relief, but a great blessing; and if I *have* to pay your bill, I shall be obliged to take all the time the court or law allows; as if any more unexpected bills come in, there may not be any "residue" to pay to the comparatively poor young lady who is to receive what remains after the estate is settled.

"You may think my language emphatic, but I can employ no milder terms in giving expression to my feelings and opinions."

RECORD OF MORTALITY FOR THE WEEK ENDING SATURDAY, FEBRUARY 27, 1892.

temporary duty. February 16, 1892. Granted leave of absence for seven days. February 24, 1892.

CARTER, H. R., surgeon. Detailed as recorder, Board of Examiners. February 20, 1892.

WHEELER, W. A. passed assistant surgeon. Ordered to examination for promotion. February 16, 1892.

VAUGHAN, G. T., passed assistant surgeon. Detailed as executive officer, Supervising Surgeon-General's Office. February 27, 1892.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held on Monday, March 14, 1892, at the Medical Library, 19 Boylston Place, at 8 o'clock P. M.

Dr. G. B. Shattuck, "Pneumonia in Boston during the Recent Epidemic of Influenza." Dr. J. W. Farlow, "A Case of Sudden Death in a Rubber Factory: Inquiry into the Effects of the Inhalation of Naphtha."

G. G. SEARS, M.D., Secretary.

THE AMERICAN MEDICAL ASSOCIATION will hold its fortieth annual session at Detroit, Mich., June 7, 8, 9 and 10, 1892. Dr. J. S. Cain, of Nashville, Tenn., will deliver the Address in General Medicine; Dr. John B. Hamilton, of Chicago, Ill., the Address in General Surgery; Dr. Charles A. Lindsay, of New Haven, Conn., the Address in State Medicine. Dr. Henry A. Walker, of East Detroit, is the Chairman of the Committee of Arrangements.

APPOINTMENT.

DR. E. M. BUCKINGHAM, has been appointed Physician to the Children's Hospital, Boston.

RECENT DEATHS.

STEPHEN CUSHING, M.D., M.M.S.S., died in Boston, February 1st, aged fifty. During the war he served as medical cadet in the army and later as assistant surgeon in the navy. He graduated from the Harvard Medical School in 1866.

HEINRICH ROSENTHAL, M.D., editor of the *Allgemeine Medizinische Central Zeitung*, died February 7th, in Berlin, aged fifty-eight.

SAMUEL G. JARVIS, M.D., of Claremont, N. H., died March 5th, aged seventy-five. He graduated from Jefferson Medical College in 1838, and since 1840 has practised in Claremont, representing the town in the legislature in 1875 and 1876.

PURVIANCE, GEORGE, surgeon. Detailed as chairman, Board of Examiners. February 20, 1892.

HAMILTON, J. B., surgeon. Detailed for special duty. February 18, 1892.

STONE, G. W., surgeon. Detailed as member, Board of Examiners. February 20, 1892.

IRWIN, FAIRFAX, surgeon. Ordered to Norfolk, Va., for

Lecture.**ON THE MECHANISM OF THE MAMMALIAN LIMB.¹**

BY HARRISON ALLEN, M.D.,

Professor of Comparative Anatomy and Zoölogy in the University of Pennsylvania, etc.

In all animals the limbs are adapted for locomotion in one of three ways, and each of these is in fixed relation to the plane of support: the first by which movement is made through air; the second by which it is made through water; and the third by which it is made on the ground. Observe, we speak of motion in air, in water, and on the ground. Flying and swimming mammals are surrounded by the medium through which they move, whereas in terrestrial mammals the limb is on the ground. The few exceptions that can be made to this statement will not interfere with its truth in general. Again the size of the limb (notably the foot) in its proportion to that of the body decreases as we pass from the flying to the walking animal.² Thus the wing of the bat in proportion to that of the body is immensely larger than are the paddles and flukes of a whale or seal, and both of these again, are larger than the foot of any of the terrestrial animals. In a word, the size of the limb disposed for progression is in direct ratio to the density of the medium through or on which the animal moves.

Let us examine the skeleton of the dog with reference to the relation which the limbs have to each other, and to the influence which is exerted upon them by the weight of the head and spine. We notice in the first place that the anterior extremity is supported entirely by muscle; for we do not acknowledge that limbs with clavicles are better adapted for support than are those without these bones, since when the extremity is fixed at a small movable point to the breast-bone it gives little or no assistance to the terrestrial movement. Indeed, the clavicle does not appear until the limb is adapted for kinds of motion with which terrestrial planes of support have nothing to do. Now, in order that the anterior limb be firmly supported, its motion precisely defined, its strength as well as its mobility rigidly preserved, these muscles must be of enormous size and power. We find that the lines of origin of this muscle-mass are secured from a large region, namely, the back of the skull, the side of the chest, the sternum, the vertebral aponeurosis and even, in some forms, the hip-bones. All the muscles which thus arise are in the forms of sheets, either simple or folded once, twice or three times. Often from a sheet we may have ribbons evolved, or from a second sheet bandage-like layers, but never thong-like or cable-like bands. These sheets are wonderfully rich in nerves, and extend to, and partially imbed, the shoulder-blade so that no part save that which lies directly at the shoulder-joint is free. They extend down along the arm at varying distances, always reaching as far as the humerus and not infrequently the wrist.

How different is everything in the hind limb! The hip-bone is fixed to the line of the spine; and the limb, not being supported by muscle-masses, has in every

part an entirely different aspect from that of the front limb, and the muscles which do arise from the line of the spine are confined to a surface scarcely any larger than that of the hip-bone, and act, of course, not on the part which is homologous to the scapula, but on the lower limb-segments. They show slight disposition to extend forward (for example, as in the possum), and scarcely any to extend backward along the caudal vertebrae, yet they preserve the same tendency, as do the fleshy masses of the anterior extremity, to send bundles down (that is, distally) to reach in most forms to points as far as the knee or even the ankle. Since the nerves are more numerous in the sheet than the spindle forms of muscles, it follows that the nerves going to the posterior extremity are relatively fewer than those going to the anterior.

Let us retrace our steps a moment to consider the two limbs from an entirely different point of view than the one above accepted. Assuming that vertebrate life found its first expression in aquatic animals, and remembering that the most important feature in the life of aquatic animals is the means by which the mechanism of respiration is adapted to the medium of water, it follows that problems of the mechanism of the limb in aquatic creatures will be essentially different from air-breathing forms inasmuch as they all possess respiratory organs which are fixed to the sides of the neck, or at least to the region back of the head, since in some types, as the fishes, there is no true neck. It will be at once seen, accepting as correct that an anterior extremity demands for high degrees of efficiency an extended surface for the origin of its muscles, that much of such surface is lost in gill-bearing vertebrates, and it is probably true that this accounts for the fact that no such forms possess large anterior extremities. Take, for example, the proteus-type of waternewt, which is the best expression known of this phase of development. We have here the gill-arches in front of the small anterior limb, and the chief motion is obtained by the action of the long flexible tail rather than by the limbs. In the frog, the gill-arches indeed disappear, yet, even here, the anterior limb remains of small size.

In mammals the relation existing between the motion of the anterior extremity and the respiratory act must be remembered. It is not accidental, I am sure, that such an extremity is placed at the side of the front of the thorax. The act of breathing is assisted by many of the muscles which move the anterior extremity whereas none of the posterior have any connection with respiration. The posterior extremity, on the other hand, is held to the line of the spine by a fixed pelvic girdle. The exceptions to this rule are so unimportant that they cannot be separately treated. Not only is each hip-bone fixed to the side of the trunk, but is also joined to its fellow at the pubis (but often excepted, and seals always), and the relations of both bones are held to be, not with respiration, but to the functions of the organs of the abdomen, especially to the rectum and the organs of generation.

We have seen that the shape of the limb is in relation to the density of the medium through which it is used, and now we will notice that in terrestrial forms the motions of the limbs hold an equally exact relation to the centre of gravity of the body. In the most rapid motion of the terrestrial type the front limb can retain its plane of support on the ground until the trunk has passed along so far as to bring the centre

¹ A Lecture delivered at the Academy of Natural Science of Philadelphia, February 19th, 1862.

The curious fact that we have one phrase to express motion through the water, which is the act of swimming, another phrase to express motion through the air, which is the act of flying, but no one phrase to express motion on the ground, is the last named motion being included in such terms as the acts of walking, running, leaping, etc.

of gravity in a line which will pass vertically upward through the foot. In a subsequent attitude of support, the hind limb can reach forward as far as or even beyond this line.

It is a remarkable circumstance that both in the anterior and posterior feet, the ground is reached by the outer border of the foot, and not as one would suppose at first sight, by the foot being brought down in a horizontal position. In all quadrupeds the outer border of the leg and the outer border of the foot receives distinct nerves. In the fore limb it is the ulnar, in the hind limb it is the musculo-cutaneous and short saphenous nerves. The outer border is further often adorned with fringes of hair, or other appendages either in the form of scutes, warts, or of special folds of skin. In a word, the outer border of the foot and leg, taken as a whole, is apt to be distinct from the rest of the body, not only in the way it is used in progression, but in its domination of nutritive processes.

The cycle of movement of the foot in the act of walking is something as follows: the foot in the first stage (that is, before being brought to the ground) is in a position midway between pronation and supination. The outer border as it reaches the ground is held in this position but for an instant, since the body surging forward by the aid of the other three legs, soon brings the main lines of weight upon the foot, which now rests on its widest surface of contact. The impact is somewhat gradually transferred to the inner border, along which, when the main body weight is beyond, the foot is lifted from the ground.

It is noteworthy that when used in any other way except for support on the ground (I mean by this firm contact against a resisting terrestrial surface), limbs of all mammals resemble one another; for example, forms so distinct in systems of classification as the sloth, the bat, the seal and the duck-mole are associated in one respect, namely, by the absence or diminution of impact of the several parts of the limbs. The characters of the bones of the arm and thigh, since they do not support the body on the ground, are almost exactly alike in the sloth and the bat. In like manner, the general outline of the scapula in man, the ape, the kangaroo and the jumping-mouse, conform to a single plan (that is to say, the supra-spinatus fossa is narrower than the infra-spinatus), since in none of these animals is the anterior extremity used for support. Likenesses which are due to strain, as in the bat and sloth, are recognizable; as well as those due to adaptation of the anterior extremity to prehension, as seen in men and the apes; or those due to adaptation to the swimming habit in creatures so far apart as the duck-mole and the seal; but all these, nevertheless, may be associated by a merely negative character, namely, the absence of impact.

When walking with a closed umbrella, using it as a cane, one brings the ferrule down on the ground at every step. A leg of a living animal periodically adjusted to the ground like the closed umbrella, is said to be modified by *impact*. In a word, it is impact that takes place in the umbrella every time it is brought to the ground. When the umbrella is held in mid-air and opened, the movement is independent of impact. An animal using its anterior extremity in a similar manner (as in a bat unfolding its wings for flight), the several parts are said to undergo *strain*. The difference between impact and strain in a general

way implies a difference in the method of progression, that is to say, the difference between strictly locomotor and prehensile use.

I will now attempt to make an application of the above stated facts, which I fear some will think radical. I allude to the study of the causes of certain fractures in the human body. May I venture the opinion that without an understanding of the mechanism of the limb in the lower animals, the etiology of lesions of the limb in man cannot be explained? The following is an example of a lesion through strain: A sailor falling from the deck of a vessel to the bottom of an open hold, catches at a rope for support; he sustains himself but for an instant; he feels a sharp pain in the region of the shoulder; he lets go his grip and again falls. Examination shows that he has fractured his shoulder-blade.²

Now the man has done exactly what a monkey will do many times a day in the forest, as he springs from swaying vine to pendant bough; but the animal incurs no risk to the shoulder-blade or to any other bone. The man has attempted something, in an excursive way, to which his structure appears to be adapted, but in the attempt he fails and incurs injury. Unless an analysis of such a lesion can be reasonably undertaken by comparing the manner in which this act can be safely performed with that which results in disaster,—in a word, of a comparison of the parts in a monkey and in man,—no exact clue to the fracture can be vouchsafed. Let me also invite your attention to a lesion by impact. Sir Charles Bell has drawn the figure of a man on a stumbling horse; the man is in the act of being thrown forward. The position of the anterior limb of the horse and that of the arm of the man are the same. In an instant afterward both limbs will come to the ground, the horse's to enter into the second stage of the foot's normal cycle, the man's to break. In placing his anterior extremity forward as though it was well adapted to move on the ground (though it has long since been adapted for an entirely different class of work), he applies it for a purpose to which it is in reality unfitness, and disaster ensues.

I have been interested in studying the position of the hand in fracture, at the lower end of the forearm. The text-books teach that the hand comes to the ground directly in the middle, or on the thumb side. I have concluded, when the body falls prone, that the hand comes down on the little finger side as is normally the case in the lower animals. An examination of the specimens preserved in museums has convinced me that this assumption is just as capable of explaining the deformation as is any other, and is sustained in addition by an examination of its literature. A short time ago I stumbled and fell. I instinctively threw the right hand forward to break the force of the fall. I found when I examined the parts that my hand was bruised along the little finger side, and the clothing soiled on the corresponding part of the forearm. In the explanation of a lesion, created as it is by an error of impact, the line of reasoning essential to it is quite different from what is met with in strain; but the problem suggested is like it in one regard, that it is profitable to the study of the manner by which the parts of a limb adapted for strain are easily disadjusted when called upon to

perform the duties of impact, and also like it in another way that it can be best explained by a knowledge of comparative anatomy.

ORIGIN OF THE RED BLOOD-CORPUSCLES.¹

BY CHARLES LOUIS MIX, A.M.

In the life-history of any mammal there are to be found two sorts of red blood-corpuscles: (1) the nucleated, found during early embryonic life; (2) the non-nucleated, found during later embryonic and throughout extra-uterine life. It is therefore convenient in consideration of the origin of red blood-corpuscles to divide the subject into two portions, the origin of red corpuscles in the embryo, and the origin during extra-uterine life. The first division naturally falls into two minor ones, the origin of the corpuscles (1) during the early stages of the embryo, (2) during later fetal life.

I. ORIGIN OF THE RED BLOOD-CORPUSCLES OF THE EMBRYO.

A. DURING THE FIRST STAGES OF THE EMBRYO.

In the very young embryo red corpuscles are nucleated cells, at first possessing a very thin layer of protoplasm often overlooked by investigators, but which later develop more protoplasm and become impregnated with hemoglobin, thus forming true embryonic nucleated red corpuscles. Embryologists differ both as to the place and method of origin, one class advocating the mesenchyma of the body of the embryo, another class the *area pellucida* and *area opaca*, especially the latter. Of those who belong to the first class the theories of Reichert, Ziegler and Wenckebach may be mentioned.

Reichert² believed that the first blood-vessel to arise was the heart, which developed from a mass of cells of which the central ones became embryonic nucleated red corpuscles, and the peripheral ones the endothelial lining of the heart. According to this theory, therefore, the blood is mesodermic in origin.

Ziegler³ thought that the cavities of the blood-vessels were developed from gaps in the mesenchymatous tissue. "The systems of blood and lymph-vessels," says Ziegler, "arise from remains of the body-cavity (gaps between the primary germ-layers), which in the universal extension of the mesenchyma remain as vessels, lacune or interstices, and which are ultimately surrounded and taken up by it." The formed elements of the blood, especially the embryonic nucleated red corpuscles, arise in various places in the lacune or gaps by rapid proliferation of the mesenchyma cells there present.

Wenckebach⁴ found that in the case of *Perca fluviatilis* the blood-corpuscles arose from a compact mass of cells, the "intermediary cell-mass," found under the

chordæ; and he goes on to say that "the cells are gradually loosened by the blood-stream and carried along by it," for he believed that heart and plasma were formed before there were any corpuscles. Later, while working upon another embryo, he discovered the origin of the intermediary cell-mass: it arises from cells which grow in between the alimentary canal and notochord from the mesoblastic somites.

In a late paper Ziegler⁵ has described the intermediary cell-mass, saying that the central cells become the first blood-corpuscles and the peripheral ones go to form the walls of the first veins. He also returns to Reichert's old view, for he says that some of the first embryonic blood-corpuscles are also formed in the heart and aorta.

Of those who claim that the *area opaca* is the true source of embryonic nucleated red corpuscles, the theories of Kölleker, Klein, Foster and Balfour, His and Rückert deserve notice.

Kölleker's theory, which for convenience may be called the solid-cord-formation theory, is really an extension of Reichert's and Remak's. Reichert believed that the first embryonic corpuscles were formed in the region of the heart; Remak disagreed with him and declared that they were formed in the *area opaca* or *sanguinea*, as he would name it, since its function is predominantly blood-formation. Kölleker, in his "Embryology," says that both of these authors are correct, and that furthermore, the first corpuscles may arise in the *area pellucida*, wherever, in fact, new blood-vessels develop. According to him the mesoblast cells found in the *area opaca* between the two primary germ-layers arrange themselves in cylindrical or irregularly limited cords which form a network, in the meshes of which there are groups of other cells forming the "Substanz-inseln" or "connective-tissue islands." At the beginning of the second day in the chick the cords become better marked, owing to the formation in their interior of a hollow limited by distinct walls. The walls develop from the superficial cells of the cords, and form the endothelial lining of the vessels; the hollow is produced by a fluid secreted by surrounding cells, which pierces the walls of the cord, forming the blood-plasma. At the points where the fluid enters the cord the cells composing the wall are pushed aside in heaps called "Blut-inseln" or blood-islands. The cells of the latter at once begin to acquire hemoglobin, and being very loosely bound together they separate easily and fall into the blood-plasma, becoming nucleated red corpuscles.⁶

Klein's⁷ theory may be styled the vacuole theory. According to him, the first blood-vessels are formed from certain mesoblast cells of the *area opaca* in which vacuoles appear. The vacuole of each cell increases rapidly in size, pushing the nucleus to one side, and crowding out the protoplasm until it is a peripheral film in which nuclei begin to appear. These nuclei then becoming differentiated into protoplasmic cells, form a wall about the vacuole which may now be regarded as the lumen of a blood-vessel. From time to time cells are budded off from the inner side of the wall, and falling into the lumen become by the acquisition of hemoglobin embryonic nucleated

red corpuscles. From the outer side of the wall nucleated processes grow out and anastomose with similar processes from other cells. By the formation of vacuoles the processes become hollow, thus forming a capillary network filled with blood. The plasma is secreted by the wall-cells.⁹

Foster and Balfour¹⁰ teach that certain mesoblastic cells of the *area opaca* called "angioblasts" develop long protoplasmic processes which unite with one another, the nucleus of the original cell splitting into a number of nuclei which lie scattered in the undifferentiated protoplasm. At the nodes nuclei accumulate, and their surrounding protoplasm becomes infiltrated with haemoglobin. The processes then become hollow, some of the central nuclei and their undifferentiated protoplasm forming embryonic nucleated red corpuscles,¹¹ the peripheral ones forming the endothelial cells, the latter secreting the plasma. "The formation of the corpuscles does not proceed equally rapidly nor to the same extent in all parts of the blastoderm. By far the greater part are formed in the vascular area, but some arise in the pellucid area, especially in the hinder part." Foster and Balfour agree with Kölle and Reichert, who claim that corpuscles arise in the heart, in that they look upon this organ as a "gigantic nodal point."

His¹² declared that the first blood-vessels develop from the white-yolk or parablast, that they then spread from the *area opaca* and *pellucida* into the body of the embryo, being filled with a clear fluid before a single corpuscle has been formed. Attached at various places upon the inner surface of the walls of the vessels are groups of cells, the blood-islands. These next break away from their attachment and fall into the circulating fluid.

Rückert,¹³ Gensch,¹⁴ and others have shown that, in the Selachians, the merocytes or parablast nuclei found at the edge of the vascular area develop protoplasm about themselves, and then divide into groups of nucleated cells, thus forming the blood-islands, which then break up into blood-corpuscles. If this method of formation be true, blood is entodermic in origin.

The five theories just given easily reduce to two, the first three forming one well-defined theory, the last two, another. The solid cords of cells described by Kölle differ from the protoplasmic processes of Foster and Balfour in only one respect: the cells of the former have a distinct outline, the cells of the latter are undifferentiated, consisting in their entirety of a mass of protoplasm containing nuclei. From what is known of embryonic connective tissue it seems probable that the observations of Foster and Balfour are correct, embryonic connective tissue cells showing scarcely any traces of walls. Both Kölle's cord and Foster's and Balfour's protoplasmic process become hollow in much the same way. Klein's formation of vacuoles, as Foster and Balfour remark, is simply another way of explaining the formation of the central hollow. From all evidence, therefore, the Foster-Balfour theory is undoubtedly a true one.

⁹ Quoted from Foster and Balfour: Elements of Embryology.

¹⁰ Foster and Balfour: Elements of Embryology, 1st edition, London, 1874; 2d edition, London, 1883.

¹¹ As Foster and Balfour state the theory, the nuclei become the corpuscles. It has been shown, however, that the nuclei in question are surrounded by a very thin layer of protoplasm. Cf. C. S. Minot, Anat. Anz., Bd. v, 1890, pp. 601-604.

¹² Quoted from Foster and Balfour: Elements of Embryology.

p. 151.

¹⁴ Gensch: Die Blutbildung auf dem Dottersack bei Knochenfischen. Archiv. für mikr. Anat., Bd. xix, p. 144, 1881.

The theory of His and Rückert is in some cases probably true, particularly in the case of the cartilaginous fishes where there is a close agreement among all writers. Notwithstanding this fact, it needs more confirmation before it can become generally accepted.

All who have written upon the formation of embryonic corpuscles agree that they possess the power of dividing by indirect division, thus forming new corpuscles. We have, therefore, in the early embryo, three well-authenticated sources of embryonic nucleated red corpuscles, (1) from the mesenchymatous cells of the body according to Reichert and Kölle, (2) from the cells of the mesoblast in the *area opaca* and *pellucida* according to Foster and Balfour, and (3) from one another by indirect cell division. There may, in some cases, be a fourth source, the merocytes or parablast nuclei.

B. IN LATER FETAL LIFE.

(1) Nucleated Corpuscles.

In the later embryonic stages the corpuscles are of two sorts, nucleated and non-nucleated. As to place of origin it is commonly agreed that they arise in the following sequence: (1) From the liver, (2) from the spleen, (3) from the marrow. Kölle, Neumann, Pox and Salviovi, and Dr. Howell all give different theories as to the method of origin.

Kölle,¹⁵ as early as 1846, held that in later fetal life the liver was the first organ to form red blood-corpuscles; and in this he was right, but in his explanation of the method, probably wrong. He taught that certain white nucleated corpuscles found in the liver become impregnated with haemoglobin, thus forming red nucleated corpuscles. The latter then entered the embryonic circulation and at a later period lost their nuclei by absorption preceded by fragmentation, thus developing into non-nucleated red corpuscles from the nucleated form. Kölle thought that the liver, after a time, began to lose its haematopoietic function, this being assumed by the spleen.

The idea that the liver of the embryo is a source of corpuscles was not a new one when Kölle wrote. In 1840, Reichert had, by a lucky guess, referred to it the function of forming blood-corpuscles, and E. H. Weber had also written upon the subject. To Kölle, however, the credit is due of being the first to give any credible description of the process.

Neumann, who believed in the haematopoietic function of the spleen when he first wrote upon the origin of blood-corpuscles in 1858,¹⁶ afterwards concluded that there is no evidence that the spleen is concerned in the formation of the embryonic nucleated corpuscles,¹⁷ thus differing from all other writers upon the subject, but he believed very firmly in the blood-forming function of the liver. In his study of that organ he found two elements, which he thought form red nucleated corpuscles, certain large liver cells and certain free nuclei. He implies that the latter assume a film of constantly increasing protoplasm, and become red nucleated corpuscles by being impregnated with haemoglobin. He describes certain liver-cells in which a vacuole forms, constantly increasing in size. In these vacuolated cells "there arise directly in the proto-

plasm or in a previously developed vacuole, new and peculiar nuclei by a free-formation process; and, by the appearance of a homogeneous yellow substance in the region about the nuclei, they give rise to the nucleated colored blood-corpuscles. These then undergo their further metamorphoses outside the mother-cell."¹⁸ It will be noticed that the nuclei of the blood-corpuscles do not arise from the nuclei of the liver-cells as Dr. Howell implies.¹⁹ In the formation of the vacuole it may be seen that this theory is very similar to Klein's.

Foa and Salvio²⁰ describe giant cells in the fetal liver, spleen, marrow and lymphatic ganglia, which they name "hematoblasts," and which split up into masses of smaller "hyaline cells" each one of which becomes charged with hemoglobin and becomes transformed into a red nucleated corpuscle. This theory will be mentioned again.

Dr. Howell²¹ believes that certain cells of the liver, lying between the hepatic cylinders, arrange themselves in solid cords which form corpuscles and vessel-walls in accordance with the solid-cord-formation theory already stated. He further found a case in which corpuscles seemed to be forming in the interior of a vein which was developing in the muscular substance of the posterior limb of an embryo of a kitten, and he therefore regards as a fourth source of embryonic nucleated red corpuscles, any region where developing blood-vessels are found. Howell believes firmly that there is but one method of blood-formation in the embryo, namely, by the solid-cord-formation theory. He says nothing about the hematopoietic function of the lymphatic system in the fetus.

(2) Non-nucleated Corpuscles.

There are three theories for the formation of the non-nucleated red corpuscles of later fetal life, of which the last two now to be given are well established; the first is very much disputed.

As long ago as 1846, Köllicker said that the nucleated embryonic red corpuscles become non-nucleated ones simply by the loss of the nuclei which disappeared by absorption preceded by fragmentation; and as late as 1890, Dr. Howell said that the nucleated corpuscles "under normal conditions lose their nuclei and become changed to the biconcave red corpuscles of the circulating blood, the transition, in the young embryo, taking place in the blood itself."

Unfortunately for the simplicity of this theory other investigators flatly contradict it, and Dr. Minot, who has tested its truth, finds no evidence in any of his numerous preparations that a nucleated embryonic corpuscle can become a non-nucleated one.²² He is the first to point out the very obvious fact that the two structures are entirely independent of each other, never being inter-transformable. Dr. Minot also says that the free nuclei, which Balfour states constitute the beginnings of the nucleated corpuscles, are not free nuclei, but are surrounded by a very thin layer of protoplasm. This stage soon gives place to a second, where the nucleus is more granular and the protoplasm increased in amount. A third stage follows, where the nucleus becomes smaller and stains

uniformly. These changes may be said to represent the phylogenetic changes in the genesis of the mammalian red blood-corpuscle, the second stage corresponding to that of Ichthyopida, and the third to that of Sauropsida.²³

Schäfer's²⁴ vaso-formative theory is firmly established, having been confirmed by many different observers, and by Kuborn²⁵ very recently. The process takes place in the vaso-formative cells discovered by Ranvier.²⁶ Unfortunately it is not a source of very many corpuscles, for it is a method lasting probably until only a few days after birth. A part of the protoplasm of connective tissue-cells, and also, according to Kuborn, of certain cells of the fetal liver, becomes impregnated with haemoglobin, condensing after a time in round globules about the volume of a corpuscle. The cells then elongate into anastomosing processes, which subsequently become hollow, containing a fluid in their interior. The hollow spaces of adjacent cells then coalesce, forming a system of capillaries; the fluid becomes the blood-plasma, and the protoplasmic globules become the non-nucleated corpuscles.

The liver, spleen and marrow are all supposed, with excellent reasons, to give rise to non-nucleated embryonic corpuscles by a method to be described in the third division of this paper.

II. FORMATION OF RED BLOOD-CORPUSCLES DURING EXTRA-UTERINE LIFE.

During extra-uterine life the corpuscles of the blood are all non-nucleated biconcave discs; they are not cells, but plastids. In some cases, as in the pig and the opossum, red nucleated corpuscles or true cells have been found under normal conditions, but generally their presence in the blood is due to some pathological disturbance.

The importance of the rapid formation of red corpuscles in adult life is shown by a simple computation. Suppose during a severe menstruation a loss of blood of 150 gms., or about 150 c. cm., the specific gravity of blood being 1,055. This loss is restored in twenty-eight or thirty days, so that in one day 5 c. cm., or 5,000 c. mm., of blood must be formed, or 208 c. mm. per hour and $3\frac{1}{4}$ c. mm. per minute. That is, 19,000,000 corpuscles are formed every minute and 300,000 every second of life for some years. This estimate does not include the replacement of the daily loss, which may, perhaps, represent another very large amount.

There have been many theories to account for the formation of corpuscles in adult life, but I shall give but five, of which only the last rests upon any sure foundation:

(1) As early as 1846 Wharton Jones,²⁷ influenced by a fancied resemblance in size and superficial appearance between the nuclei of the white corpuscles and the red corpuscles themselves, thought that the latter were to be regarded as simply the extruded nuclei of the former. There was no histological evidence to support this view, so that it never received any credence.

²³ Since non-nucleated red corpuscles are not cells, and since they are in no way related to embryonic nucleated red corpuscles, Dr. Minot proposes to call them "blood-plastids." The term is a very convenient one, but I believe the old terminology is too firmly established to be thus replaced.

²⁷ Wharton Jones: *On the Blood-Corpuscle Considered in its Different Phases of Development*. *Philosophical Transactions*, 1-46, p. 63.

(2) Previous to 1868, the date of Neumann's first paper on the origin of the blood, there was a general belief that red corpuscles were formed from the white by the loss of the nucleus and the acquisition of hemoglobin during circulation. Even Neumann and Bizzozero, following Köllecker and other preceding investigators, said in their first papers that it was from leucocytes that red corpuscles developed. Later they both retracted their assertions since they could not find any transitional forms, and to-day the time-honored theory is completely abandoned.

(3) Arndt,²⁹ who wrote much more recently, thought that in cases of strong anaemia portions of red corpuscles broke off and developed into new ones. Such a method of origin and growth seems directly opposed to the first principles of biology, and consequently the theory has never been accepted.

(4) Hayem,³⁰ who may be called the rediscoverer of the blood-plates which he named "haematoblasts," regarded them as young red globules incompletely developed, originating from the protoplasmic portion of the white, colorless corpuscles of the blood. Since "haematoblasts" are always found in increased numbers after direct loss of blood as in hemorrhages, or after indirect as in fevers, or in chronic anaemia, he thought he had a sufficient argument to show that they are young corpuscles in process of development. Hayem³¹ also finds another origin of his haematoblasts in the interior of the vaso-formative cells of Ranvier and Schäfer. Neumann³² declares that Hayem has described under the name of haematoblasts two entirely distinct structures, (1) colored haematoblasts which are merely broken-down red corpuscles, and (2) uncolored haematoblasts or true blood-plates. Hence Neumann concludes that it is not at all strange to find increased numbers of haematoblasts in diseased and anaemic persons, for it is in those persons that the most active destruction of red corpuscles takes place. Pouchet,³³ who has written a great deal of useless matter upon the subject, began by believing the haematoblasts of Hayem to be derived from leucocytes. His final view was that they arise in the plasma of the blood as the result of a process something like the formation of fibrin. It is needless to say that the theory never received any attention. Like Hayem, he thought that haematoblasts develop into corpuscles. This theory of Hayem's has received some support from Feuerstuck,³⁴ as he regards Hayem's haematoblasts as young forms of the white blood-corpuscles, which latter become impregnated with hemoglobin, thus forming red corpuscles. However, Hayem's theory may be said to-day to be almost completely abandoned.

(5) The theory which prevails at present is, without doubt, the true one. It is that red corpuscles develop from the so-called "erythroblasts" found normally in the marrow of the bones, in the fetal liver and rarely in the spleen and lymphatic ganglia of the adult. This theory is so extensive that it forms the third portion of the paper.

THE RELIEF OF SALPINGITIS BY DILATATION AND DRAINAGE OF THE UTERUS.¹

BY CHARLES P. STRONG, M.D.,

Assistant Surgeon, Free Hospital for Women; Physician to Out-Patients, Massachusetts General Hospital; Assistant in Gynecology, Harvard Medical School.

THE treatment of salpingitis is divisible into two general classes: operative, that is, ablation of the tubes, and non-operative. Of the former I say nothing except that the larger the experience of the operator the less the percentage of cases will be found which demand this radical measure. Of the latter class we have still in daily practice the use of alternative applications and vaginal tamponades, as the common and routine measures. There will be found, however, many cases in which this antiphlogistic treatment is unsatisfactory, securing only temporary alleviation, or, from other necessities of circumstance being impracticable.

I wish to present for consideration an intermediate measure which does not embody the objectionable features of either of the two methods sketched above.

Considering for a moment the etiology of salpingitis, exclusive of malignant and tuberculous diseases, or direct violence, it is from the uterus the causative agent extends into the tubes, whether this be of a highly septic, or mildly irritant, nature. This is especially true of those cases where the marked characteristic is alternating periods of quiescence and activity of inflammatory symptoms. These cases are distinguished by the presence of more or less profuse uterine discharge, and examination will always reveal endometritis existing in some one of its several forms. Obviously, if this endometrial condition be restored to normal before the tubes become in themselves hopelessly diseased, and before the co-existing salpingitis has induced peritoneal adhesions, a return to healthful conditions may be expected.

The local treatment of endometritis by applications through the barely patent cervical canal, must always be both dangerous and unsatisfactory. This has been demonstrated too often, clinically, to require further comment. The treatment by drainage of the uterus following free dilatation, has much to commend it as a safe and conservative measure. That it is practised by but few is due, I think, not to non-success following its procedure, but rather to the glamour attendant upon a primarily successful laparotomy. I have selected four cases among the number in which I have performed it, to illustrate the various phases of cure, palliation and temporary improvement, and one case of acute endometritis and salpingitis, to show the freedom in which the measure may be employed in cases which we are prone to consider dangerous, if meddled with. The first three cases were operated upon sufficiently long ago to make the present report of value, the most recent one having been under observation considerably over a year. To avoid unnecessary confusion, I have selected only those cases with symptoms which would be materially affected by improvement in the salpingitis or endometritis; also, statements with regard to local conditions are based upon the results of examinations made with the patient anesthetized.

CASE I.—Mrs. K. This patient was referred to me for operation upon the cervix and perineum, for relief of the symptoms of backache, constant pain in ovarian

¹ Read before the Boston Society for Medical Improvement, January 11, 1892.

region, and repeated attacks of slight pelvic peritonitis, subsiding coincidently with the establishment of profuse purulent discharge from the vagina. The patient was a complete invalid, and had been bed-ridden most of the time.

October, 1889. I found, by examination, the left Fallopian tube enlarged quite uniformly to the size of an ordinary sausage; the right tube about one-half that size — numerous peritoneal adhesions which were not dense enough to prevent mobility of the tubes. Both ovaries apparently normal. The uterus the seat of a decidedly puriform endometritis, and in a hyperplastic condition.

I rapidly dilated the uterus, removing the thickened mucous membrane, which was very rich in its glandular elements: thoroughly disinfected the cavity, and packed with iodoform gauze. Drainage was continued one week.

November 22d. Examination showed that the right tube had diminished one-third in size. The left tube was practically normal. The uterine discharge was re-commencing. The operation and treatment was repeated.

May 6th. There had been great improvement in the symptoms of six months previous, and it was only at my request that the patient had reported. Upon the right there was still a distinctly enlarged tube. Operation repeated.

August, 1891. Twenty-two months had elapsed since the first operation, during which period there had been no local treatment. I found the right tube still slightly enlarged; the left normal. No evidence of endometritis. The uterus involuted to its proper size, and the cervical laceration not requiring operation. During the two years there had been no attack of peritoneal inflammation, and the symptoms of pelvic disturbance had been so alleviated that the patient had resumed all her household duties, and considered herself well. I, however, have classed this case at present as one of complete relief rather than cure, as the slightly enlarged tube may possibly, but not probably, at some future time give trouble.

CASE II. Mrs. F., married eighteen months, and confined to bed during the past six months by pain in the left side. Had for sometime previous to marriage a slight discharge from vagina, which is steadily increasing.

Examination, under ether, shows decided enlargement of left tube, possibly also of right. Ovaries normal.

December 11, 1889. Treatment as in Case I.

January 9th. One month later, more comfortable than at any time for a year. Only two attacks of pain since the operation, each one less than thirty minutes duration; can walk about fifteen minutes, and stand five minutes, without inducing more than a temporary feeling of pain in the side. Operation and treatment repeated. At this examination the enlargement of the tube could hardly be recognized as pathological.

January 5, 1892. One year from the last operation. Patient is perfectly well; is totally free from any pain or discomfort in the pelvis. Examination can detect no enlargement or tenderness of the tubes on either side. Walks several miles daily; no endometritis whatever. This case I consider a cure.

CASE III. Mrs. Mary K., nurse. Pain in both ovarian regions, steadily increasing for several years, despite replacement of a retroflexed and adherent ute-

rus. Chronic and profuse purulent endometrial discharge. Not able to work.

October 14, 1890. Examination shows a decided mass on left side — less upon right side; ovaries not felt. Implicated in the mass were the tubes, possibly the ovaries; certainly, there existed an abundance of strong peritoneal adhesions. Operation and treatment as in previous cases. Hypertrophied mucous membrane, and numerous mucous polypi removed. Immediately upon leaving the hospital this patient went to work in the violent ward of an insane hospital, needless to say, against advice. She re-entered the hospital three months later. I could not see that the local condition had been improved, and operated, removing the tubes and ovaries on both sides, which were so firmly imbedded in adhesions that they were torn away piecemeal. This case I consider a failure. I have reported it as illustrative of those cases in which this palliative treatment does not afford reasonable prospect of success. At the time of the operation, I did not regard it at all as a hopeful case, and so stated; but as a possibly conservative measure, I decided to try what might be accomplished.

CASE IV. Mrs. F. F. This case was one of acute salpingitis accompanying acute gonorrhoeal endometritis. There was great dilatation of the tubes. I operated three times in two weeks. At the conclusion of the attack both tubes remained enlarged. There was a re-lighting of the salpingitis after the interval of a year, when I repeated the operation. Three years ago, that is, five years after the first operation, there could be detected only some slight thickening about the broad ligaments, which was not at all tender, and to-day the patient is, so far as symptoms are indicative, perfectly well. I am aware that my course in operating upon this case in the height of an attack of acute gonorrhoeal salpingitis, exposes me to criticism: but it was necessary to do something as the patient's condition was becoming decidedly worse hourly. Laparotomy could not be considered; other palliative measures had been tried in vain. The course I adopted seemed the only one possible.

As to the methods of procedure. The aim should be to render the operation thoroughly aseptic, operating with the patient upon the side in the Sims' position, avoiding any downward traction of the uterus, by which the tubes might be put upon the stretch, and possibly a portion of their contents forced out upon the peritoneum; the cardinal point in the whole operation being to avoid lighting up fresh salpingitis or peritonitis by mechanical violence. Dilate slowly and steadily with steel forceps until the canal will readily admit a No. 36 sound. Thoroughly scrape away by sharp curette and currlette forceps the entire uterine mucous membrane, both cervical and fundal: especially endeavoring to free the opening at the uterine end of the tubes, it being at this point that they are frequently occluded by a slight hyperplastic enlargement. Disinfect the uterine cavity. Insert a twisted roll of iodoform gauze, about the size of a goose-quill, to the fundus. Along side of this roll insert others until the cervical canal is firmly filled. Leave the protruding ends within the vagina, and protect the vulva by an antiseptic pad. Change these rolls of gauze every two or three days for ten days, and keep the patient in bed a week.

The time of election for the operation is one week subsequent to the menstrual flow. Examine, under

ether, after a month has gone by, and if there is still evidence of salpingitis or endometritis, repeat the treatment. Should the tubes be enlarged when the uterine interior shows no evidence of disease either by mucopurulent discharge or hyperplasia, do not operate, but rely upon douches and alterative applications to the vaginal vault, to effect reduction in their size, which may, very possibly, be due to the results of the peritoneal inflammation, rather than to any increase in the contents of the tubes.

Selection of cases for operation. Success depends upon a proper appreciation of the pathological conditions which are to be relieved. Acute cases are best treated, for a time, at least, by palliative measures, or by radical operation. Chronic cases in which the tubes are tied down by many adhesions, and in which the symptoms are dependent upon immobility of the tubes, or of the uterus, do not afford a hopeful prospect of cure.

In all other forms I consider the operation not dangerous, and capable of accomplishing far more in the way of radical cure than any of the absolutely palliative measures, and, of course, free from the one great objection of a radical operation. The symptoms are indicative, in a measure, of what you may expect to find by examination. Pain, which is the constant and prominent symptom, is usually constantly present in those cases where peritoneal adhesions are thick and strong. These are not promising cases. The duration of the disease is also of importance. Those of more recent origin, other points being equal, yield more readily. Mobility of the tubes, and patency of the uterine end of the canal, are absolutely essential. It will be noticed that none of my cases have been cured by a single treatment. I think this is due to the practical difficulty of removing entirely the affected uterine mucous membrane. Whether a longer period of drainage would accomplish this, I am unable to say. I have made it a rule to limit my drainage to eight or ten days.

The suffering caused by the operation and the treatment is practically nil. An incidental point gained is that it tends very strongly to relieve menstrual pain, especially in those cases where the pain is due to mechanical obstruction to free menstrual discharge.

With regard to the dangers of the operation, there are none if properly planned, properly executed, and proper judgment employed in guiding the convalescence.

A REPORT OF THREE CASES OF CRANIOTOMY.¹

BY GEORGE HAYEN, M.D.

CÆSARIAN section, under the brilliant leadership of Stengnér, is so rapidly taking the place of craniotomy, in Germany, that I have thought the following cases sufficiently interesting to present to the Society this evening; and hope that the discussion will give us the sense of the members upon these two operations. These cases all occurred at the Boston Lying-in Hospital during the month of September.

M. H., entered on the 9th and gave the following history: Two years ago, was pregnant for the first time. The labor was very difficult, and she was only

delivered after many hours by instruments. The child was stillborn. As a result of this labor, she had a recto-vaginal fistula and a vesico-vaginal one. She was operated upon three times for these injuries. The vesico-vaginal fistula was closed; not so the recto-vaginal. She was told by the doctor who operated upon her to present herself at the hospital if she should ever be pregnant again, at the seventh month. This she failed to do. Examined when she entered, there was found to be a complete tear of the perineum through the sphincter. Just above the sphincter, there was a bridge of tissue across the anterior border of the anus. Above this was an opening which admitted two fingers into the rectum. There was, just below the cervico-vaginal junction, two dense bands of cicatricial tissue, running from the posterior to the anterior vaginal wall. These were supplemented by smaller bands running in various directions. The examining finger found some difficulty in passing this obstruction. Pelvic measurements were as follows: Crest, 10 $\frac{1}{2}$ inches; spines, 9 $\frac{1}{2}$ inches; external conjugate, 6 $\frac{1}{2}$ inches; internal diagonal conjugate, four inches.

I saw the patient for the first time at ten o'clock, A. M., and thinking that the bands of cicatricial tissue offered a very formidable barrier to delivery, asked Dr. Townsend to see the patient with me, which he kindly did, and agreed with me as regarded the serious aspect of the case. We thought that the rupture of the bands, which was inevitable, might open the peritoneal cavity. Dr. C. M. Green was asked to see the case, and at three o'clock we examined her under ether, and it was finally decided to try high forceps. The os was nearly dilated; the membranes were ruptured, and the cicatricial bands were dilated as much as possible with the hand. Forceps were applied with great difficulty, and with axis traction, the head was brought through the superior strait, and down to the bands, where it was firmly fixed. Firm and steady traction failed to advance it, and it was decided to do craniotomy. Even then, it was with great difficulty that the head and body were delivered. The patient made a good recovery.

Examined before discharge, there was a bi-lateral and deep tear of the cervix. The perineum and sphincter were gone, and the tear extended for about two and one-half inches up the anterior rectal wall.

The next case is that of M. A., colored. She had rickets, and did not walk until she was four years old. Pelvic examination gave the following results: The symphysis was very thick and projective in a rostrum; the sacrum was apparently wedged downward and forward between the ossa-innomina; the promontory was about on a level with the symphysis. Measurements were: Crests, 9 $\frac{1}{2}$; spines, 9 $\frac{1}{2}$; external conjugate, 6 $\frac{1}{2}$; diagonal conjugate, 4. The true conjugate was probably less than three inches. The hand introduced, found itself much crowded in all directions, and the closed fist could with difficulty be passed through the pelvic inlet.

I did not see the patient until evening. The pains had been very strong during the afternoon; but there had been no advance of the head. Ether was given, and with great difficulty, forceps and traction-rods were applied; but steady, firm traction failed to engage the head. Dr. Townsend was kind enough to be present, and repeated attempts by both of us resulted only in failure. Version was thought of; but, owing to the very thin

¹ Read before the Boston Society for Medical Improvement, January 11, 1892.

lower uterine segment, and the almost certain necessity of perforating the after-coming head, it was thought best to do craniotomy. Even then, delivery was very difficult, and the shape of the head when born left no doubt regarding the impossibility of delivering it through the natural channel in any other way. The patient left the hospital on the sixteenth day, well.

The third and last case differs from these, in so far as there was no obstacle to delivery in the pelvis or vagina; the whole trouble being with the uterus.

The patient was admitted on the 16th of September. She had been at the hospital two days before this, but was not supposed to be in labor. She said, however, that she had had pain off and on ever since she was first seen. Fifteen hours after entrance, the os was fully dilated, and the membranes ruptured. The head was high, position posterior. The pains were very severe at intervals of about five minutes.

No advance being made, I was sent for; ether given. The head was found movable above the superior strait; was rotated to an O. L. A., and after some difficulty, forceps and rods applied. Steady traction failed to produce any result. After several attempts, I sent for Dr. Townsend. Forceps with him resulted as they had with me, in failure; the head would not budge; the uterus being simply drawn down somewhat into the pelvis.

We now attempted version. There was a dense contraction ring which held the child firmly between the head and shoulders. The head was held exactly as it would be in a pillory.

We endeavored for hours to dilate this ring sufficiently to pass the hand through and by the head; but the most we could do, was with great difficulty to touch a knee with one finger. The feet were evidently high up in a contraction pocket. We then endeavored to shave the head back through this ring, but without success. A pulseless cord was found, and craniotomy resorted to. Powerful traction with the cranioclast merely served to pull away the skull piece by piece, until finally there was nothing left but the atlas. The hand could now be introduced, and the foot was finally brought down. Extraction was most difficult. With a blunt hook in the groin, and with traction upon the legs sufficient to break the bones, delivery was finally accomplished.

The first two of these cases, I think, could very properly have been treated by Cesarian section, and in the first one, it seemed to me at the time the operation of election, and does so still. If the tear had extended through the anterior vaginal wall, and so into the peritoneal cavity, a fatal result would have been probable. As it was, the tear went in the most favorable direction; namely, towards the rectum. It does, however, seem to me that the mother's chances were better with Cesarian section than with craniotomy. I have not seen her since she left the hospital; but, with the tear which she had, and with the history of having undergone several previous operations, much tissue having at each time been lost, I think that her outlook for a perineum and sphincter is very dubious.

In the second, we had to do with a pelvis through which a fair-sized child at term could not be born, and the question here is, what was the best operation for the mother? Staeger's results have been so brilliant, that it seems to me the time has come for us to think pretty seriously of his operation. Statistics are only reliable when the operation has been done by a good

operator, under the most thorough aseptic precautions, and before all other methods of delivery have failed. These statistics Dr. Reynolds and myself hope to present in another paper.

The third case was very peculiar. The woman had probably been in labor for forty-eight hours before entering the hospital. The uterus was in a state of tonic contraction, which ether and hours of labor failed to overcome. The cord had become pulseless, and craniotomy was certainly indicated. The body was, however, so firmly held by the uterus that traction merely served to pull the head to pieces without budging the trunk. Version, if possible, seemed the best thing to try. If we could bring a leg down, it gave us a wedge; and continuous traction for a length of time, would probably allow the body to pass the barrier. This proved true, but how difficult it was, can only be realized by those engaged in the case. Dr. Townsend succeeded in getting one leg, but not until he had brought down the other could any advance be made and even then not without the help of a blunt hook which I inserted in the groin.

I sincerely hope that these cases will provoke a discussion on this subject. If they do not do so, I shall have failed in my object in reporting them.

Clinical Department.

TWO CASES OF APPENDICITIS WITH ABSCESS, SUCCESSFULLY TREATED BY RECTAL PUNCTURE.¹

BY MAURICE H. RICHARDSON, M.D.

On Wednesday, November 18, 1891, I was called by Dr. Porter, of Auburndale, to see Mrs. H. S. P., aged about thirty. Dr. Porter gave me the following history:

"Last Friday night I first saw her. She was suffering with colic and indigestion. She was in pain and was out of her head. She vomited once or twice. I tried to move the bowels with enemas without success. The next morning the pulse was 125 and the temperature 101.5°. I gave her an anodyne. She had pain in different parts of the abdomen. On Sunday she began to complain of pain in the right iliac fossa. With the movements of the bowels we got various seeds in large quantities. Day before yesterday it looked like appendicitis. I began to give her small doses of calomel, which moved the bowels. On Monday night she passed about a drachm of various kinds of seeds. Yesterday she began to have tympanites. The pulse yesterday came down to 100, and the temperature to 99.6°. This morning she had two movements of the bowels. On examination of the abdomen I found that it was dull in the right flank, and by rectal examination there was a bunch which could be felt also by the vagina."

I found the patient lying in bed looking fairly well. Tongue was coated and white. There was no distension of the abdomen, though it was everywhere tympanitic, and nothing could be felt by external examination. By the vagina, the uterus seemed to be somewhat fixed, and there was a resistance to the right. I found a great prominence in the rectum behind the bladder, caused by a tumor, which was soft and evidently con-

¹ Read before Boston Society for Medical Improvement, January 11, 1892.

tained pus. The general condition of the patient was good. After careful consideration, I advised that the tumor be punctured and drained through the rectum.

On the following day Dr. Porter, under ether anesthesia, punctured the abscess through the rectum, and left in a drainage-tube. This was followed by perfect recovery in about three weeks. She has remained well ever since.

On Monday, December 14, 1891, I was called to see a young man, living in South Boston, by his physician, Dr. W. J. G. Fogg, from whom I obtained the following history :

"James W. B., aged twenty-six, brass-finisher, was perfectly well up to a week ago last Friday night. Then, about bedtime he began to feel uncomfortable, and complained to his wife of distress in the bowels, with a slight bellyache. He slept fairly well that night. Took some breakfast the next morning, and went to work. He had a good operation of the bowels. In the middle of that forenoon he was taken with severe cramp in the belly (indicating the place by putting his hand over the lower part of the abdomen, below the navel). He did not pay much attention to it at that time. The pain lasted all the forenoon, and he was not able to get back to work. On Saturday he stayed at home. He had great pain in the lower part of the abdomen on the right side, accompanied by vomiting. His tongue was dry and red. Respiration was difficult and increased in frequency. Pulse was 88 and temperature 101°. Had had a slight chill. That was on Sunday morning. On Monday his pulse went up to 130 and to 128 in the evening. The pain was somewhat controlled by Squibb's opium, fifteen drops every two or three hours. The belly was increased in size and somewhat tender. Respiration seemed difficult, and he vomited continually. The next day the pulse dropped to 98, and there was a little less tenderness. He was stupid and heavy from the opiate. Vomiting and nausea the same. The next day, Wednesday, pulse was 94 in the morning, and rose to 103 in the evening. General symptoms about the same. On Thursday the pulse was 105 in the morning and 100 in the evening. During this time we were giving him very small quantities of milk with carbonated water. He could not take any stimulant, although lately he has taken some. The next morning the pulse was 90, but otherwise he was about the same. On the 12th, that is, two days ago, his pulse was 98, and the treatment the same. There was vomiting all this time. Yesterday the pulse was 105 and in the evening 100. He was vomiting hard, retching and straining all day. There was a little coozing of fluid from the bowels. During this time he was passing gas at intervals. There was a little hesitancy in making water yesterday, which amounted to retention last night. He was catheterized this morning. The last twenty-four hours ending this morning, we have made no attempt to give any nourishment at all. He cannot retain it. During his whole sickness he has not taken a pint of milk in twenty-four hours, though milk has been the main-stay. The distention reached its maximum within the third day. There has been no discharge of pus at all. In regard to the pain he said that there has been no very severe pain since the third day. There has not been as much pain as one would expect to find, and there has been no chill. Respirations are much better now. They were nearly sixty a minute at times. The vomiting

has ceased since morning and he has had a large defecation."

On physical examination I found the young man's general appearance good. His face was rather flushed, pupils large, abdomen slightly distended. There was a dulness in the right iliac fossa. Bladder was full. Pulse 104. Tongue a little red. No special tenderness except on deep pressure in the right iliac fossa. Tympanitic everywhere except in this place, where it was a little dull. Nothing could be felt by the rectum.

In this case it seemed to me best to wait, because the symptoms had taken so decidedly favorable a turn. Everything went on well for a week, when vomiting returned with renewed violence, accompanied by increased pain, tenderness and distension. He was sent into the Massachusetts General Hospital on the evening of December 23d, and I saw him at about eleven o'clock that night. I found him vomiting constantly, with a high pulse and temperature, and in a very bad general condition. There was a large tumor occupying the lower part of the abdomen, filling the whole right and extending far into the left side. There was a large, tender mass pressing upon the rectum just back of the bladder. The patient's condition was so bad that anesthesia and laparotomy were out of the question. I therefore introduced a long rectal trocar of small diameter into the tumor. There was an immediate discharge of fetid pus. The canula was fastened into the mass and a large antiseptic dressing applied. During the night the vomiting ceased and about two quarts and a half of pus escaped through the canula. At the dressing in the afternoon the canula became displaced. From that time to the present the temperature has been normal and the physical signs have entirely disappeared. Nothing can now be felt by the rectum.²

I think there is no doubt that I was wrong in advising delay in this case. It was not evident at the time, however, and it is only in the light of subsequent events that an error of judgment becomes manifest.

Several times before I have been inclined to open abscesses pointing in the rectum by that channel. It seems to me that it is often more dangerous to open such abscesses by laparotomy and that the drainage is not so good. While as a general principle I believe it is far better to open from above, for obvious reasons, yet at times it seems to me that this procedure cannot be adopted. If the patient is in a very bad condition, the necessary shock of a laparotomy is often sufficient to cause a fatal termination. If the abscess has not become definitely adherent to the anterior abdominal wall, it is undoubtedly very dangerous to drain the cavity upwards.

In the first case quoted there was everywhere tympanic resonance, and there was no reason to suppose that the tumor had become adherent to the abdominal wall, nor was it possible by this route to drain the abscess except by going between the healthy intestines. In the second case the patient's condition was too serious to entertain for a moment the question of laparotomy, no matter how quickly or how skilfully performed. I recall several cases in which I have no doubt whatever that the patient died from the shock of an operation performed at this time.

In both the above cases pus was about to break into the rectum, and the operation hastened by a few hours the process of Nature. The chief objection to this

² He remains perfectly well at the present time, March 9, 1892.

method is the infection of the abscess cavity by the rectal contents. In these two cases nothing of the kind took place, and it is a well-known fact that abscesses break into the rectum without any subsequent trouble. We must bear in mind, however, that at times long-continued suppuration, general wasting, and death result from the breaking of an appendicular abscess or from the rupture of a pus-tube. Such cases, which are most disastrous and distressing, have led us, when possible, always to open large collections of pus in the pelvis by laparotomy, notably in cases of appendicitis and salpingitis. In the latter condition, with which I have had considerable experience, I have yet to see any ill results following vaginal puncture and drainage. It is obvious that while we have in rectal puncture the most dependent drainage, this method should be selected only in very exceptional cases. In vaginal drainage I think we have a less dangerous method, although in my experience it is very difficult to make the utero-vaginal canal aseptic. I believe in avoiding both as far as possible, but that occasionally we must resort to this procedure.

In a case very similar to the second, which I saw with Dr. Goss two years ago, and which I sent to the Massachusetts General Hospital, Dr. Warren drained by the supra-pubic method. The rectum was compressed by a large abscess situated directly behind the bladder. This case made a good recovery, although in the light of my recent experience I am quite convinced he would have done just as well by rectal drainage.

While there is no definite rule to be laid down in these cases, it seems to me that a certain number of them may be more safely drained in the manner described.

WOUND FROM WHIP-LASH SIMULATING BULLET-WOUND.

BY FRANCIS C. MARTIN, M.D., ROXBURY, MASS.

I HAVE had a case recently, which is certainly an amusing curiosity. A wagon-driver presented himself, with an enormously swollen under lip, and the following history: Late in the evening, he was driving through Dover Street, past a dense crowd of people. He struck his horse with the whip, and, at the same instant, there was a sharp report, and he felt a stinging pain in the chin. He found a wound in the lower part of the chin, and another smaller one inside the mouth at the base of the lower lip. The next morning the whole lip was very much swollen.

On passing a probe inwardly, from the outside of the face, I found a passage through into the mouth at the smaller wound. The probe rubbed against some hard substance *in transitu*. All the appearances indicated a severe bullet-wound. On making a free incision from the inside wound, I cut down on the foreign body, and with bullet forceps removed a black mass, about as large round as a lead pencil, and over half an inch long. I at once exclaimed, "You were shot from the crowd!" On dropping the object, however, from the forceps, into a basin of water, it went rather slowly to the bottom, without any "thud." I then examined it carefully, and found it was a piece of the whip itself.

I have often seen the power of the long snake-whips of the freighters in Montana, in taking out the skin in

minute pieces from any part of a mule, with unerring accuracy, but never heard of any such catastrophe as the one I have described.

Medical Progress.

RECENT PROGRESS IN DERMATOLOGY.

BY JOHN T. BOWEN, M.D., BOSTON.

AN EPIDEMIC DERMATITIS AT PADDINGTON INFIRMARY AND NEIGHBORING INSTITUTIONS.¹

In view of the probability so often expressed, that many forms of cutaneous inflammation heretofore classed as eczema or dermatitis simply, are due to the action of a parasite or its products, the following epidemic of dermatitis is interesting and suggestive.

At the meeting of the Medical Society of London, held on November 30, 1891, Dr. Thomas Savill read a paper on "A Recent Epidemic at Paddington Infirmary." Between July 1st and October 23d, 163 of the 846 inmates of the infirmary were attacked by the disease, or twenty per cent. Only two cases occurred among the staff, the author himself and a housemaid. The disease is described as a universal dermatitis always resulting in a desquamation of the epidermis, attended by a certain amount of constitutional disturbance but no essential rise of temperature, running a course of about six weeks, and attacking males slightly more often than females. The disease sometimes began as a papular or papulo-erythematous eruption, sometimes as elevated macules, in rare instances in ring forms; in either case becoming confluent in a week's time, and presenting then the features of an acute, desquamating dermatitis. In a majority of the cases there were vesicles also, which caused much serous exudation when broken. The eruption started most frequently on the upper portion of the body, although the lower portions were affected first in a considerable number of instances. It seemed to spread by contiguity to the adjacent parts from those first affected. Burning and itching were constant features throughout the attack. Convalescence was slow, and 38 of the patients had relapses. Anorexia and prostration were the chief constitutional symptoms. In about a quarter of the cases there was vomiting, diarrhoea, or both. Temperature normal excepting occasionally at the height of the inflammation. The conjunctive were inflamed in all of the severe cases, and the hair and nails were often lost in the later stages of the disease. Albumen was found in the urine in fifty per cent. of the cases, but no serious renal disease was recorded. Some cases ended fatally [proportion not stated, nor whether these were the old and enfeebled.

—Rep.] chiefly from "the extreme weakness produced by the eruption," in other instances from collapse following the vomiting and diarrhoea. Some died comatose as in uremia. In several cases boils and carbuncles were seen scattered over the surface. The disease bore, on the whole, the most resemblance to an acute general eczema, differing from it, however, in the extent of the inflammation and thickening, in the profuseness of the exfoliation, and the definiteness of the course. Germicides externally and stimulants, afforded the most relief. With regard to the etiology, age was found to be a predisposing condition, the largest pro-

¹ *Lancet*, December 5, 1891.

portion affected being between 60 and 70 years old. The author considered that the clinical phenomena alone were almost enough to prove its contagious character, especially its definite course, the constitutional disturbance, the marked effect of germicides, and its epidemic character. Further pathological and bacteriological investigations were promised.

At the same session Mr. Lunn described a similar epidemic dermatitis as occurring at the Marylebone Infirmary from May 1891, when 193 persons were affected. He considered that 10 deaths could be directly attributed to it. No light could be shed on its etiology, after a most painstaking investigation. It occurred in wards that had been newly cleaned and isolation failed to secure exemption. Several attacks were noticed in some instances. Nothing unusual was detected in the several autopsies that were made. Mr. Lunn made the interesting statement that he noticed that if the first patch that appeared were painted with collodion, a further spread of the disease was avoided.

Dr. Richards of the Hanwell Institution, in the same district as the Paddington Infirmary, said that beginning with July 1st they had had 38 cases of the epidemic, or three per cent. of the inmates, the last case occurring in October. All of his patients recovered. He thought the eruption of a neurotic character and probably due to influenza, although he admitted in reply to a question, that there were no other manifestations of the influenza at the time, with the exception that in some of the cases there was a history of pain in the limbs, headache, etc.

Dr. Stephen Mackenzie said the outbreak, as far as his own experience was concerned, was quite unique. The features were those of an universal erythema with copious desquamation. He pointed out the similarity of these cases to the rare sporadic forms of dermatitis exfoliativa, which we have no grounds for considering contagious. In this outbreak he thought that there must be some special causative conditions in the environment, and as he had always regarded eczema as a purely local disease, he was ready to accept any bacterial theory upon sufficient grounds. He suggested that the clothing may have had some share in the spread of the epidemic.

Dr. Crocker was in doubt whether the disease was a constitutional one, like the exanthemata, or a local disease, the general symptoms being merely incidental. In a considerable number of cases he had noticed an enlargement of the glands, and this was not in proportion to the intensity of the dermatitis. The disease usually began with one patch, and became general, a feature often seen in pityriasis rosea. Against its being a general disease was the fact that it was endemic rather than epidemic.

DRYING LINIMENTS IN THE TREATMENT OF SKIN DISORDERS.

In February, 1891, Dr. George T. Elliott, of New York, published an article in the *Journal of Cutaneous and Genito-Urinary Diseases*, on "Bassorin Paste," a new base for dermatological preparations. The formula for this preparation was not disclosed, but it was stated to consist of Bassorin, a substance derived from Bassora gum tragacanth, and other sorts of gums, combined in proper proportions with water, glycerine and dextrine, so as to form a jelly-like mass that dries on exposure to the air. This was proposed as a substitute for the gelatine preparations of Pick and UBBE-

on the ground that the disadvantages of gelatine were obviated by the new preparation. Almost any drug may be incorporated with this base, which he names Bassorin Paste, and which he has found useful in a variety of cutaneous affections.

On May 8, 1891, Professor Pick, of Prague, read a paper on the use of drying liniments (*linimenta exsiccantia*)² in the treatment of skin diseases. These so-called liniments were designed for the same purpose as the Bassorin Paste of Elliott. The disadvantages of gelatine as a protective dressing for the skin are several. In the first place it has to be warmed, and it requires some little skill in order to hit the right moment for spreading the gelatine in a smooth layer upon the skin. It may be properly done by a skilled attendant, but it is difficult for the ordinary out-patient to effect it. More important still, the medicament is not brought into sufficiently close contact with the skin, on account of the rapidity with which the gelatine hardens. To obviate these difficulties Pick proposes tragant, a substance that fulfills the necessary conditions. Numerous experiments have convinced him that the proper consistency is obtained by the following formula:

Tragant	:	:	:	:	:	5 parts.
Glycerine	:	:	:	:	:	2 parts.
Ag. destill.	:	:	:	:	:	100 parts.

This is best prepared by warming, as in this way a completely antiseptic preparation is obtained, that will keep without the addition of antiseptics. He remarks that the drug of commerce often varies so much that it may be necessary to alter the proportions of the constituents. The "liniment" that is thus prepared can be used like gelatine in all cases where a protective covering is desired, it can be applied in a thin layer like an ordinary liniment or ointment, and can be completely removed by a simple washing. The first sensation experienced is a pleasant coolness, which is especially marked in erythematous and inflammatory conditions. An advantage over fats and plasters is that the greasy feeling is avoided, and that the clothing is not liable to be stained. This simple liniment may be used as a base for the exhibition of active substances. Drugs that are soluble in water, are added directly to the water that is necessary for the preparation of the liniment, while insoluble drugs are rubbed up with the mass. The oily substances, such as the tar preparations, ichthyol, styrax, Peruvian balsam, etc., do not change the essential properties of the liniment, except when used in very large amounts. Other insoluble substances, as chrysarobin, oxide of zinc, white and red precipitate of mercury, iodoform, salicylic acid, etc., give the liniment the consistency of a paste according to the amount used, without diminishing its drying and other properties. Two properties deserve especial emphasis: first, that the liniments do not become altered when used for a long time, and secondly that most substances when vigorously used locally, give rise to almost no unpleasant general results. Tar liniments of a strength of ten per cent. have been used over the whole body, without producing any, or very slight, symptoms of absorption. Pick declares that in a generalized eczema or psoriasis, the whole body may be treated by a five to ten per cent. tar liniment, — a procedure that would be dangerous when the drug is used in the form of an ointment, or an alcoholic or ethereal solution.

² Archiv. f. Derm. u. Syph., 1891, 4 Heft.

In recommending the liniments to the trial of physicians, Pick disclaims all wish to extol them to the exclusion of other methods of treatment, as many cases will be far more improved by our present method with ointments and plasters.

INFECTION FROM GLANDERS.

It has long been known that glanders or farcy may be transmitted from the horse to man, and many instances may be found scattered through the literature, more or less faithfully described. But little attempt has been made, however, to bring together the differential characteristics that separate glanders, especially in its more chronic forms, from affections that offer a clinical resemblance. In view of the great progress that has been made in the etiology of the disease by the discovery of a specific bacillus, it would be strange if our knowledge of its clinical aspects were not rapidly increased, and the careful studies recently made by several French observers illustrate once more the value of bacteriological experiment.

M.M. Hallopeau and Jeanselme^{*} report very fully a case of chronic glanders, which can be merely outlined here. The patient was a man of thirty years, who entered the St. Louis Hospital in April, 1889. He had been a wagoner for six years, and was accustomed to take care of his horses himself. While caring for a sick horse, that was subsequently killed, he was seized with febrile attacks accompanied by violent pains in the joints and in the head, and the nasal secretions became increased. Soon after he developed an inflammatory swelling on the crest of the left tibia, which was opened at the hospital of Chalon-sur-Saône, and was followed by a suppuration at this point which lasted for three years. Later, there appeared abscesses upon the arms and legs which opened spontaneously or were incised; but as the wounds refused to heal he came to Paris, and entered the St. Louis Hospital, where the lesions were finally healed after vigorous cauterization with the thermo-cautery. He then remained well for three years, when he presented himself again, complaining of severe headache, with some deafness and pain in the ears. Examination showed an ulceration upon the vault of the palate, which spread rapidly, soon involving the gum and the upper lip. At this time he was placed upon antiphilic treatment, which was stopped after six weeks, as no improvement could be detected. Soon afterward, the patient being troubled with a sort of chronic coryza, there was found to be an ulceration of the mucous membrane of the nostrils, with fistulas leading to the bones. Cauterization of the ulcers was then tried, with the result of partially healing the ulcerations upon the palate. The ulceration upon the lip is described as irregular at its edges, dentated in some places, circinate in others. The edges were everywhere sharply cut, and in some places prominently raised as in epithelioma, but they did not possess the hardness so characteristic of cancerous growths. The floor of the ulcers was extended by prolongations beneath the edges, and was constantly covered with a glistening exudation, in the midst of which appeared yellowish elevations, looking not unlike pustules. The pains in the head now became more intense and had a marked nocturnal character, preventing sleep, and the ulcerations upon the lip extended, until the whole upper lip had been destroyed. Abscesses then appeared upon the

arm and hand, which left obstinate, ulcerating surfaces. Suddenly, one day, the whole face became the seat of an inflammatory edema, the surface being covered with rounded pustules, which began at the angle of the right eye, where the lacrymal sac had been for some time in a state of inflammation. This acute attack, which was accompanied by a high temperature, subsided after the sloughing away of a large part of the right nostril, and was succeeded by an enormous tumefaction of the lower lip, which had hitherto been spared, and the patient died soon afterward in a state of general marasmus.

Three periods are to be noted in this case: (1) Symptoms of an infection, increase in the nasal secretions, and numerous abscesses. Then an intermission of three years. (2) A new series of abscesses, ulceration of the nasal fossae, the vault of the palate and the lips. (3) An attack of acute glanders, which ended fatally.

In cases of glanders analogous to the one described, the diagnosis is almost always suggested by the patient's occupation, as it almost never occurs except in those who are often brought into contact with horses. That cases of indirect infection may occur, however, is illustrated by that of Elliottson, where a washerwoman died of the disease after washing the linen of a coachman who had had the affection. The principal lesions are multiple abscesses and ulcerating neoplasms. Characteristic of these abscesses is their site; almost all are situated on the extremities. Some of them open and cicatrize rapidly, while others, and these are the most numerous, are chronic in their course and the resulting ulcer very difficult to heal, and inoculations made from these two varieties proved that the bacillus of glanders, when it has its seat in the human tissues, has a very variable period of existence. The fluid from the abscesses may sometimes have a characteristic aspect; it has an oily, gummosus appearance, is often streaked with dark colored blood and is called by veterinarians "huile de farcin." The acute inflammatory edema which ushered in the last stage of the disease, the authors regard not as an erysipelas, but as an attack of acute glanders, such as often terminates a chronic farcy.

The experimental studies in this case proved conclusively the nature of the affection, as the bacillus of glanders was obtained in pure cultures, and the disease inoculated upon animals.

Cauterization with the thermo-cautery was the only treatment that proved in any way effective. By this means the external manifestations were delayed for a period of three years, and in the same way the ulcer of the palate was healed.

In the same journal is published a communication to the French Society of Dermatology, by Besnier, on the same subject, in which another case of glanders is described where a severe ulceration of the face developed in the course of a chronic farcy. The patient was a man, twenty-five years of age, who had been a groom, wagoner and driver. He entered the St. Louis Hospital in May, 1890, presenting in the centre of the face lesions that he said had existed for only five months, and which gave the impression at first glance, of a severe syphilis. He had contracted the disease four or five years before its fatal termination. The first symptoms were of a pulmonary character. For more than a year he suffered from a severe and incessant cough, with night-sweats, abundant expectoration, loss of appetite, of flesh and of strength.

^{*} Annales de Derm. et de Syph., tome II, No. 4.

Eighteen months or two years later all these symptoms had disappeared. There then appeared an abscess of the left forearm, together with lesions in the nasal cavities. Upon entering the hospital the centre of the face was the seat of an uninterrupted series of infiltrations, ulcerations and losses of substance, which had destroyed a large part of the nose and of the upper lip, exposing the gum. The vault of the palate was totally covered with ulceration. Wherever an active lesion was seen it was situated upon a red infiltrated base. Upon this developed the elementary lesion of glanders, the "bouton farcineux," a small papule, which rapidly softened with the formation of small yellow centres, which emitted an abundant puriform liquid. The open surface thus formed increased rapidly with irregularly indented edges, but in a few days this mode of progression ceased, and the ulceration became undermined with infiltrated edges. It was by the coalescence of several of these ulcers that the large losses of substance were formed. Considered separately, each of the proliferations has but a limited duration, and a process of cicatrization goes on at the periphery. In this way there is formed in the midst of the vast ulcerations a characteristic mass of nodules and projections of every size and shape, that gives the whole an irregularly granular and wormeaten appearance. Later, the process at first rapid, becomes slow, the lesions always secreting a quantity of yellowish pus which fills the depressions and never ceases, so long as the lesion is active. The patient had not at any time symptoms of nasal trouble; no coryza nor exudation. Antiphylactic treatment proved futile. Iodiform and camphorphilic naphthol were the most useful means found for checking the suppuration and limiting the formation of the farcy nodules. At the time of the patient's entrance, ten months before his death, a nephritis with paroxysmal oliguria was present, and he finally died from uremia. The diagnosis was confirmed by experiment, as positive results were obtained by culture and by inoculation.

Babes, of Bucharest, publishes in the *Archives de Médecine Expérimentale et d'Anatomie Pathologique*, No. 5, 1891, some observations on glanders from which we extract some of the more interesting results. After speaking of the morphology and methods of culture of the bacillus, he refers to its penetration into the sound skin and mucous membranes. In one case he discovered the existence of small reddish papules which the patient declared to be the starting points of the ulcers, and in fact the development of the ulcers from these papules could be traced microscopically. Examination of these papules showed that many of the hair follicles were hypertrophied and surrounded by a cellular infiltration, and their centre was filled with enormous masses of the bacillus of glanders, well stained by the appropriate methods. In the parts of the skin surrounding the follicle, a few bacilli were found, chiefly in the lymph channels. From this it is concluded that the specific bacillus can gain entrance to the hair follicles, there multiply and produce a dilatation of the follicle, and finally pass through the epithelial lining membranes into the adjacent tissue. In order to determine if the bacillus may gain entrance through the sound skin in animals also, Babes mixed the bacilli with vaseline, lard or lanoline, and rubbed this mixture thoroughly for two to three minutes into the skin of guinea-pigs. Glau-

ders was produced in one of three cases. Cultures of different ages, or obtained from different cases, showed very variable degrees of development. Rabbits inoculated in the ear with the platinum wire from a fresh culture, often die of glanders, without tubercles or abscesses, but with lungs congested and bacilli in the blood. Glanders in man is comparatively frequent in Roumania, so that Babes was enabled to study several cases, of which four are described. It was not always easy to isolate the bacillus of glanders, on account of the frequent association of other forms of bacteria. From a study of the chemistry of the morbid products the following conclusions are reached: (1) The bacillus of glanders produces chemical substances of a toxic nature. (2) These substances were obtained by precipitation with alcohol, or by dialyzation of the cultures in bouillon or potatoes, filtration and dissolving in water or glycerine. (3) These substances are of a brown color, and analogous to those obtained from cultures of tuberculosis and diphtheria. They possess a pyretic and toxic action stronger than that of tuberculin. The active substance is called "mälléine." (4) Neither the part that is soluble in alcohol, nor the chloroform or ether extract of the alcoholic precipitate, has any appreciable action upon the organism of animals. (5) The active product produces after injection a transient fever, often convulsions, and in large doses nephritis and general marasmus; it never produces glanders. (6) It is much more violent in action upon animals affected with glanders than upon healthy animals. By beginning with small doses, and awaiting the disappearance of the fever, a preventive vaccination may be obtained, and the disease cured, although it is difficult to determine the proper dose. The author does not wish to draw absolute conclusions from these observations, but expresses the hope that a further study of these substances will suggest a rational method of treatment for this terrible disease.

(To be continued.)

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

G. G. SEARS, M.D., SECRETARY.

ANNUAL Meeting, Monday, January 11, 1892, the President, DR. FREDERICK I. KNIGHT in the chair. DR. C. P. STRONG read a paper on

THE RELIEF OF SALPINGITIS BY DRAINAGE OF THE UTERUS.¹

DR. F. H. DAVENPORT: I have been very much interested in this subject because, as Dr. Strong has said, although there are many cases which can be successfully and satisfactorily treated by the ordinary methods of tampons and douches and applications, yet there are a certain number of cases where these measures are insufficient, and yet in which it is inadvisable to operate. I have never tried this method Dr. Strong has described, but it seems to me to possess many advantages, so that I certainly shall try it in suitable cases.

I think the question of the character of the discharge

¹ See page 258 of the Journal.

is an important one. In cases of thickening of the tube it does not always follow that the discharge that comes from the uterus comes from the tube itself, and I think I have seen cases where there was an intermittent character to the discharge where the discharge came from the uterus alone. In those cases, of course, it is more apt to be connected with menstruation, either present just before or just following the flow, and where the discharge comes from the tube the presence of pain, as a rule, is a distinguishing point; still that does not always follow. I have seen cases of uterine colic lasting a day or two set up by a slight exacerbation of the trouble in the endometrium alone. Still, where the attacks of pain are evidently due to exacerbation of the trouble in the tubes, and such pain is accompanied or followed or relieved by a flow of pus or mucopurulent discharge with enlargement of the tube, it is safe to infer that the tube is at fault. I would like to ask Dr. Strong whether he would not avoid in these chronic cases the stage of acute exacerbation for his operation. He spoke of operating in one acute case. I did not understand whether during the acute stage or immediately following an acute attack.

DR. STRONG: That was the first case I ever did. It was an acute gonorrhoeal case. The tubes were filling up, and it had been a question of laparotomy, which the family were not willing to consider; so as I felt the tubes might burst and let pus into the peritoneal cavity, I operated in that case with a view to drain the tube. The first operation was attended with so much relief that when the temperature rose again I operated again, and again the third time. I should do that if it came to a question of laparotomy quite fearlessly.

DR. G. H. WASHBURN: I have used this method in one case of this kind with very satisfactory results. It was a case where there was an evident patency of the uterine end of the tube, and the difficulty was that the opening was apparently not free enough, and the endometritis that was present was tending to close up the tube. The pain was increasing, and there was a question of a coming laparotomy if things were allowed to go on. The usual methods of different applications were tried without relief, and then I dilated thoroughly, following out the course Dr. Strong has described; I had to use the dilatation and curetting only once, keeping the canal open, however, for quite a while afterwards, longer than the ten days. I kept the iodoform gauze pencils in the uterus for three weeks, changing them every second day, and brought about perfectly free drainage of the tubes. This relieved the symptoms, and the patient has been very comfortable in that respect. That was about two and a half years ago, and the patient has not been troubled with the symptoms since.

DR. DAVENPORT asked whether at the time of the operation any extra paralyzing of the uterine fibres is necessary by an extra amount of dilatation, or merely enough dilatation is employed to just admit the sound?

DR. STRONG: I simply carry it up to that. When I get it up to No. 36 sound I think that is far enough. I dilate with Schultze's dilator. Beyond No. 36 I think there is a chance of tearing it into the broad ligament.

Incidentally, one of these cases I reported to-night was sterile and had suffered from dysmenorrhœa all her life. That is another point in favor of the operation, I think.

DR. G. HAVEN read a paper entitled

THREE CASES OF CRANIOTOMY, DONE FOR DIFFERENT REASONS, DURING THE MONTH OF SEPTEMBER, AT THE BOSTON LYING-IN HOSPITAL.²

DR. C. M. GREEN: I saw one of these cases, the first one reported, and found it of interest from the fact that we do not often see in these days such marked cicatricial stenosis of the vagina. The interesting feature in the case was largely one of deciding what had better be done under the circumstances, and I think there was no difference of opinion among the three gentlemen who saw the case that it would have been a proper and legitimate operation, from a scientific point of view, to have done Saenger's Cesarean section. We ought to have saved the child and mother too by that operation. To be sure the mother got well as it was, with a very serious tear, but, of course, the child was lost. The reason which largely controlled the decision in the consultation was a prudential one. It happened at the time the hospital was in a condition of confusion, owing to rebuilding. We were not in a condition to place the patient in such a way that she would have a fair chance after opening the abdomen, and did not feel it was quite right to the patient or to the reputation of the hospital under the existing circumstances to undertake that operation. The statistics after craniotomy on the mother's part, in good hands and with aseptic work, are entirely satisfactory. No mother ought to die after craniotomy in careful hands. There was the question of fetal life. The child was living, and it would have been more scientific obstetrics if the abdomen had been opened and Cesarean section performed.

The second case was very interesting. Operation was called for by the pelvic contraction. It seems to me that that would have been an entirely suitable case for Cesarean section had the child been living. In fact, Boston will fall behind other cities if she does not recognize the fact that under modern surgical methods and aseptic treatment the Cesarean operation is an entirely justifiable one in the hands of those who have had surgical training, and know how to do the operation.

The third case was one of unusual difficulty. Whether or not that case would have been as favorable for Cesarean section I am less certain. The condition of the uterus was very peculiar. We know that the child is often grasped by contraction rings, and the ring causes a certain amount of resistance to the extraction of the child, but it is very certain that the contraction ring should not still remain as tightly contracted as this after prolonged etherization. These rings relax in my experience. Whether or not in that third case after Cesarean section the mother would have had a good chance is questionable. With the uterus in that condition I do not feel sure that the operator would have been able to suture the uterus and obtain a good result.

DR. C. W. TOWNSEND: The record of three craniotomies within such a short time is certainly appalling, but the necessity of either that operation or Cesarean section was forced upon me in all these cases which I had the fortune to see with Dr. Haven.

In the first case, Cesarean section would, as is seemed to me at the time, be the only method of saving the child; for to drag the intact head by main

² See page 260 of the Journal.

force through the bands of cicatricial tissue in the vagina would have surely resulted in serious, if not fatal, injury to the mother.

The third case is interesting and instructive in teaching us to be on the lookout for the exhausted and irritated state of the uterus which leads to the formidable hour-glass and contraction ring. In this case there was also a thinned lower segment caused by retraction, the line between this segment and the thickened upper part forming the so-called ring of Bandl or the retraction ring. This thinning of the lower segment added, of course, to the danger and required us to use great care in manipulation for fear of rupture. It might be added that the three cases all made normal recoveries, and it seems to me that with proper antiseptic precautions such results should always be obtained in craniotomies. Statistics recently published have, I believe, borne out this statement, a great contrast to the sepsis so generally expected after craniotomy in former times. It seems to me that the remarks of Dr. Haven on Cesarean section are very timely.

Dr. GREEN: I should like the opinion of some of the gentlemen present as to whether we have the right to do a Cesarean section without the formal consent of the husband. In Dr. Haven's first case the husband was not accessible. Provided three good men think the prognosis is good for the mother, with a reasonable probability of saving the child, would they be justified in performing the operation without the consent of the husband or the next in authority? It is a question we ought to be able to decide, because there generally is not time to wait. If we would succeed with a Cesarean operation it must be done early, and not after forceps and version have been tried.

Dr. MINOT: My own opinion is that if after a formal consultation of the physicians attached to the hospital it was decided that the patient's interest required imperatively any operation, in the event of inability to obtain the consent of the husband or nearest friend, it would be their duty to operate at once.

Dr. WARREN: As a rule, I have been in the habit of waiting for some relative in case of an operation at the hospital, but under circumstances somewhat different from those Dr. Green has mentioned. When a patient is brought in in an intoxicated condition or somewhat confused from an accident and is unable to give an intelligent answer, as a rule, I have endeavored to postpone operating until some formal consent of the relatives has been obtained. I can conceive of a case that would come to me as a hospital surgeon where the question of performing laparotomy for intestinal obstruction might arise, and delay be productive of fatal result, where I should feel authorized to operate. I think the cases are quite exceptional, however. I should try very hard in all cases to obtain the consent of some relative or do the operation with a thorough understanding on the part of the patient.

Dr. GREEN asked whether or not the institution would be liable for suit if its officers were to perform a serious operation like opening the abdomen for any purpose without the formal consent of somebody.

Dr. M. H. RICHARDSON: Last week a surgeon of one of the smaller hospitals near Boston was brought into court to answer to a charge of malpractice. He had amputated a leg it was alleged, in the first place, without the consent of the father; in the second place he had done it unsuccessfully. The case was an emer-

gency case. The evidence showed that the father was in the room at the time of the operation. It was alleged that the operation was done too soon, that no operation should be performed under six hours. The jury brought in a verdict acquitting the physician. I have seen a great many malpractice suits tried. I do not believe that a verdict can be brought against a physician or a hospital for a Cesarean section, if the physician thought it was necessary, provided the patient was unconscious and no friend was present. I believe it is pretty clear that in a general hospital or lying-in hospital that, if no friends are present at the time, physicians are expected to do the best they can for the patient. I don't believe in this special case myself that a physician would be justified in doing an operation which is not acknowledged by all to be the best thing to do, without consent. I think it is a very important question, and one we have to decide for ourselves in all hospitals. I believe the important point is go ahead and do the best you can for the patient without any idea of suit. I have seen at least two cases in which the surgeons had an idea they might be sued in which that very act was the most potent thing used against them.

Dr. STRONG: I don't see why the question proposed by Dr. Green does not apply to what they did do. They operated and used their best judgment. They did craniotomy.

Dr. HAVEN: I agree most fully with Dr. Green regarding the third case. It was certainly not one where Cesarean section would have been thought of, everything but the uterus being in a normal condition. The contraction ring was, however, so firm of work as to produce any effect upon it. We worked from ten o'clock P. M. until dawn, and delivered then only after the head had been completely pulled to pieces by the cranioclast.

Dr. H. F. VICKERY: The English say that chloroform will relax more completely than ether. I wonder whether chloroform would relax such a ring?

Dr. HAVEN: I have never used chloroform.

TUMOR OF THE FEMUR.

Dr. WARREN: I have here a large tumor of the lower part of the femur of about nine years' standing. The patient was a male, thirty-nine years of age, in general good health. After some blow or strain he felt a swelling above the knee, and the femur grew gradually until it attained an enormous size, which it had when he came to the hospital for operation last Saturday. It was one of those oval-shaped tumors springing from the shaft of the femur and running up the shaft. This one was peculiar from its very dense structure, a bone-like hardness. On amputation it proved to be in the centre a soft sarcoma, and the hard part appeared to Dr. Whitney to be chiefly a calcification rather than ossification of the part. The wound healed throughout by first intention.

Dr. M. H. RICHARDSON reported

TWO CASES OF APPENDICITIS WITH ABSCESS TREATED BY RECTAL PUNCTURE.²

Dr. WARREN: I saw the second case at the hospital and the convalescence was all that could be desired. It seems to me a desirable method of dealing with certain types of these cases. The fashion now is to make an incision through the abdominal wall,

² See page 263 of the Journal.

but it is well to remember, too, abdominal abscesses can be treated in other ways.

DR. STRONG: I should like to ask whether in the first case he could detect any sign of pus by vaginal examination.

DR. RICHARDSON: No. It was impossible. There was increased resistance in the right.

DR. STRONG: In quite a number of cases that I have seen in the various hospital clinics of long standing suppuration with a sinus leading into the rectum, it has been impossible to get good drainage. I believe thoroughly where you are sure that the abscess cavity is a single one and you can reach it through the vagina, in aspirating and draining that way rather than do a laparotomy, but with regard to opening into the rectum, I think the point is one to be very seriously considered for the reason I stated. I have seen very many very long suppurative cases, the patient wasting away and dying. My remarks relate rather to the remarks at the end of the paper than to the cases.

DR. RICHARDSON: I have distinctly limited this operation to certain conditions. I have recognized in the paper the disadvantages of the procedure. I do not advocate it except in very rare conditions. I do not think that any surgeon of any judgment whatever would have subjected the second case to any other operation. I am positive as I can be that the anesthesia of a laparotomy would have killed him. I have seen them die time and again after that operation. I do not mean to say that rectal drainage is not dangerous, and that we do not have these disastrous consequences. I do not believe that rectal drainage is as dangerous as laparotomy where the patient is moribund.

THE NEW YORK ACADEMY OF MEDICINE. SECTION ON PEDIATRICS.

MEETING of February 11, 1892. WM. P. NORTHrup, M.D., Chairman; FLOYD M. CRANDALL, M.D., Secretary.

A CASE OF SPINA BIFIDA.

was presented by DR. A. JACOBI.

The patient was two months of age, and the tumor, which was present at birth, was growing rapidly. The wall was becoming thin over the central portion, and without operation would soon burst and the child die. There was also talipes valgus, and the sutures and fontanelles were very large.

A demonstration was given by DR. M. PUTNAM JACOBI to prove the fact that when the lung is collapsed, percussion yields tympanic resonance, but when extremely inflated, exaggerated pulmonary resonance.

DISCUSSION ON DIPHTHERIA.

DR. JOSEPH E. WINTERS read a paper entitled
**THE BEST APPARATUS AND BEST DISINFECTANT FOR
USE IN MOUTH AND NOSE.**

The author assumed that the disease is caused by the Klebs-Loeffler bacillus: that it is primarily a local disease. The microbes elaborating in the membrane exude a poison which is absorbed and carried into the circulation, the germ itself not being found in the blood or tissue. A point of vast importance in treatment is the fact that the specific germ on a perfectly healthy membrane does not provoke diphtheria. The primary

indication, then, is not only to cleanse and disinfect the parts but to destroy the germs *in situ*.

The activity of the Klebs-Loeffler bacillus is impaired by even weak solutions of carbolic or boracic acids. The practical deduction from this is that at the outset we should attack the exudate or culture soil in order to prevent the microbial products from producing constitutional results. It is never safe, however, to employ means that will irritate the surrounding parts, for fresh points of infection are thus made. The only means of successfully disinfecting the throat and preventing sepsis is by irrigation.

For this purpose the child should be placed on the side of the crib and a rubber sheet arranged to catch the drippings, but he should under no circumstances be lifted from the horizontal position. If a Davidson syringe be used the cleansing will be more complete, and will meet with less resistance than with any other apparatus. The irrigating should be done through the nostrils, for they cannot be tightly closed like the mouth, and with the first flow of fluid from the nose into the throat the mouth is opened and everything is discharged through the nostrils and mouth. It is occasionally necessary to syringe through the mouth. In this case the tip should be removed and the tube passed along the inner side of the cheek behind the last molar to the pharynx. In ordinary cases irrigation every two hours is sufficient, in severe cases it must be practised every hour, day and night.

For this irrigation nothing has proved as satisfactory as a ten per cent. solution of peroxide of hydrogen or a saturated solution of boracic acid. The passages must be thoroughly cleansed at each washing, and one-half to one pint of solution will be required.

In the local treatment of diphtheria is included medicated steam from a croup kettle, and the inhalation of sulphurous-acid gas through the burning of sulphur candles. For medicating the water in the croup kettle, add to one pint of water one ounce of spirits of turpentine and two drachms of oil of eucalyptus. In the use of the kettle plenty of rubber tubing is necessary, and a gas stove is the best means of generating the heat.

DR. H. D. CHAPIN read a paper on

QUARANTINE AND DISINFECTION IN LIMITED APARTMENTS.

The management of diphtheria in tenement-houses formed the chief subject of consideration. The furniture should be removed as far as possible and the child placed on a cheap cot instead of a bed or sofa. The mother, if she must also attend the rest of the family, should wear a wrapper, which can be removed upon leaving the room. The area of contagion, when ventilation is good, is small, probably but a few feet. If the germs can all be destroyed *in situ*, there will be no contagion. Old cloth or pieces of cheese cloth should be used about the patient and burned as soon as soiled. All articles of bedding should be shaken on the roof and exposed for a considerable time to sunlight and air, the two most powerful antiseptics at our command. The walls should be washed down with a sublimate solution, 1 to 1000, and the same should be used in sinks and closets. Papered walls may be cleaned with stale bread crumbs. The burning of sulphur, while it may not be of great efficacy, is undoubtedly of some value. It leads to thorough subsequent ventilation at least. The throat and nasal passages of the other children of

the family should be frequently sprayed with mild antiseptic solutions.

DR. L. ENMETT HOLT read a paper upon,

FEEDING IN DIPHTHERIA: METHODS OF FORCED FEEDING.

In a disease like diphtheria, where the principal cause of death is asthenia or exhaustion, no question can exceed in importance that of nutrition and stimulation. The most common error in this direction is over-feeding and over-stimulation during the first few days. It too often happens that when the critical period arrives the over-burdened stomach refuses to do its work. The subject may be considered under these three heads: (1) Character of food and stimulants, (2) frequency of administration, (3) forced feeding.

As to character of food little need be said except to condemn two articles frequently allowed, ice-cream and jellies, which interfere with taking more valuable food. The main reliance must be upon milk diluted according to the age of the child. Next to milk, beef broth, mutton broth, expressed beef juice, soft boiled eggs, milk toast, wine whey, oat meal or barley gruel. Junket with a little wine added, and kumyss, when the child will take it, are valuable additions to the list.

In regard to the stimulants, brandy is best, but we must be guided by the child's whims and give what he will take best.

Experiments with stomach washing show that the stomach is rarely empty sooner than two hours after a meal. It is a safe rule never to give food requiring digestion oftener than this. Stimulants and pre-digested food may be allowed at shorter intervals. The quantity of food given should be somewhat less than the child would take in health. It is best not to begin stimulants until they are indicated by the pulse or prostration, but they should then be pushed until the desired effect is produced, the only limit, in many cases, being the tolerance of the stomach. Unlike food, they should be given in frequently repeated doses. A careful record of the exact amount of food taken and retained should always be kept that we may know where we stand.

It sometimes happens that the child absolutely refuses all nourishment and stimulants. Coaxing, threats and commands are alike futile. Efforts to compel the child to take milk in teaspoonful doses results in the wasting of an immense amount of strength while little or nothing is accomplished. It is at this juncture that the question of forced feeding arises. Rectal feeding in young children, owing to irritability of the sphincter, is almost impossible. Much more efficacious, and with far less disturbance to the patient, is forced feeding by the mouth or nose. The difficulties are surprisingly small. The ordinary apparatus for stomach washing is all that is required, the method of procedure being the same as in that process. Unless there is much resistance the mouth is to be chosen. Completely peptonized milk is to be preferred. The operation should be repeated once in four hours. In this way a proper amount of nutrient can be introduced with far less worry and resistance than by the spoon method.

The operation was demonstrated upon a child of ten months, a sufficient amount of milk being introduced in about ten seconds.

DR. A. JACOBI spoke upon the subject of CONSTITUTIONAL TREATMENT IN DIPHTHERIA.

He has been convinced of the value of bichloride of mercury in all forms of the disease, especially the laryngeal. He gives it in large doses; a child of six months will take a quarter of a grain a day with no untoward symptoms. Diarrhoea is rare, and is quickly checked by a few drops of paregoric. Stimulants should not be delayed until signs of heart failure appear, for when that condition has once developed the patient is almost certainly lost. Very large doses are sometimes required, and they should be increased until an effect is produced. The doses of digitalis, camphor and alcohol, as stated in the text-books are no guide whatever. If rejected by the stomach, they should be given hypodermically. One part of camphor dissolved in four parts of sweet almond oil may be given hypodermically with but slight local disturbance.

DR. AUGUST SEIBERT demonstrated his method of **SUBMENBRANEOUS ANTISEPTIC INJECTIONS.**

If the Klebs-Loeffler bacillus generates a poison within and underneath the pseudo-membrane, that is the place to attack it. He has therefore devised an implement consisting of a number of hypodermic points set closely together on a small disc by which an antiseptic may be injected beneath the membrane. As an antiseptic, he employs very strong chlorine water. The method has now been in use eighteen months with strikingly surprising results. It is designed to supplement, not to displace, other local treatment, the injections being made but once a day, one or two, as a rule, being sufficient.

DR. VINEBERG approved of sulphurous-acid gas as it gives marked relief to the patient.

DR. J. LEWIS SMITH used a stronger solution of peroxide of hydrogen than that proposed by Dr. Winters. Stronger solutions can be used in the throat than in the nose.

DR. STOWELL thought that the strength of the solution must be graded to suit the case. Peroxide of hydrogen if too strong will cause irritation.

DR. HOLT said that in a personal trial he had found a ten per cent. solution too strong for comfort.

DR. C. W. Allen described a screen of plain glass which he had seen used in Germany. It is held before the patient's face during the examination of the throat. It does not obstruct the view and is an admirable protection to the physician if the patient coughs.

THE CHAIRMAN urged that, inasmuch as we now know the specific germ which causes diphtheria and its habitat, we definitely consider what remedies are for its destruction, and what are for the simple comfort of the patient; that the physician spend his time destroying the germs which are thrown off directly from the patient's mouth, and less to blaming sewer gas and germs constantly floating in the air.

DR. FLETCHER has made a series of examinations in tenement-houses and had found the specific bacillus in the air in a number of instances. In one house four cases developed on different floors along the same line of pipes.

Physician. — You seem to cough this evening with less difficulty.

Patient. — No wonder; I have been practising all day. — *Pharmaceutical Era.*

Recent Literature.

Leprosy. By GEORGE THIN, M.D. London: Per-
eival & Co. 1891.

In his preface the author of this book states that one of its chief objects has been to "systematize, for the convenience of the medical profession, the knowledge that has been acquired up to the present time relating to the bacillus leprae, its relations to the pathological changes peculiar to leprosy, and its important bearings on the etiology of the disease; and at the same time to place clearly before the reader the amount and nature of the evidence which can be adduced to show that leprosy is contagious." These objects have been well fulfilled in the little book before us; and it can be warmly recommended to any one who may wish to acquaint himself, at the least possible expense of time and trouble, with the best modern views of the nature of this disease.

The chapter on "history" bears the marks of careful compilation and much erudition, although it is somewhat longer and more critical than would have been looked for in a work of this kind.

With regard to the great prevalence of leprosy in India, — a subject that has of late aroused much interest in Great Britain, leading to the formation of the leprosy commission, — Dr. Thin says there can be no question, although it is impossible even to approach to accuracy in forming an estimate of the numbers of those affected.

The clinical appearances of the two types of leprosy, tubercular and nerve, are sketched with tolerable clearness, although we miss in these chapters, the vivid, sharp-cut picture that a very few writers on dermatology are able to produce with a few descriptive words.

In discussing the pathology of leprosy, the author records his conviction that the bacilli may be distinguished from those of tuberculosis by their microscopical aspects simply, in that the former are more unequal in breadth than the tubercle bacilli, and have a special and characteristic tendency to become club-shaped at one end and tapering at the other. The tubercle bacilli, on the contrary, have a fairly uniform thickness throughout. These are distinctions that have not hitherto been emphasized by observers, and should be verified with the utmost care. With regard to "giant cells," the author says he has not met with them in leprosy, with the exception of some shown him by Dr. Abraham, which he was convinced were nothing but the altered coat of blood-vessels. Typical Langhans giant cells such as are found in tuberculosis, are not, as a rule, seen in leprosy, but the large "lepra zellen" of Virchow are often referred to as giant cells, and of these Thin makes no especial mention. He ranges himself on the side of most other competent microscopists in declaring the proposition of Unna, that the bacilli are not, as a rule, enclosed in cells, absolutely untenable.

The chapter entitled "Is Leprosy Contagious?" we consider the most important in the book, in view of the reluctance evinced by so many medical men, in accepting what seems to us to need no further proof. Sixty-eight instances collected from various sources, are briefly mentioned, where the evidence of transmission of the disease from one individual to another is either conclusive, or extremely strong.

The chapter on the hereditary hypothesis is also well written, the author concluding that in the absence

of proof the hereditary theory must fall, and with the establishment of the contagiousness of the disease, it is no longer necessary even as an hypothesis.

Isolation, in Dr. Thin's opinion, is to be practised with all possible care, although he appreciates the difficulties of carrying this out in a perfect manner. After pointing out the favorable influence of the law passed in Norway in 1885, rendering the segregation of lepers compulsory, he declares his belief that the best hope for India lies in the education of the people to a better understanding of the contagious nature of the disease, and in offering them every facility either for removal to an asylum or for isolation in their homes. We believe that the chief good to be accomplished by the leprosy commission, is an elaboration of the methods by which these aims, so well defined by Dr. Thin, may be attained.

Leprosy and Vaccination. By WILLIAM TEBB. London: E. W. Allen. 1891.

This little pamphlet, written by a layman who is an opponent of vaccination in general, endeavors to show that compulsory vaccination has been responsible in great measure for the spread of leprosy in recent years. The author accepts the theory that leprosy is a bacterial disease, and considers at some length the evidence that it may be inoculated. He also shows that there is good reason for the belief that it may sometimes be transferred from individual to individual by vaccination — a proposition that would be combated by few possessed of any knowledge of the subject. What he does not prove is that vaccination is the chief factor in the spread of the disease, his evidence on this head consisting largely of the general impressions of merchants and medical men in the countries where it is endemic. While no scientific man would agree with the writer that vaccination, as well as all experimentation looking toward the discovery of better methods of treatment of leprosy should be discontinued, it must be conceded that the greatest care in performing the inoculations should be observed; and that the writer, while overstating his case, as is customary with all reformers, has rendered some service by his advocacy of the transmissibility of leprosy from individual to individual.

Botany: A Concise Manual for Students of Medicine and Science. By ALEX. JOHNSTONE, F.G.S. Lecturer on Botany, School of Medicine, Edinburgh. With 164 illustrations and a series of floral diagrams. New York: D. Appleton & Co. 1891.

This manual of 250 pages is intended as a textbook for a student who is at the same time taking a university course in Botany. It is not an elementary work and it is too condensed to be in itself interesting reading. It begins with a concise description of the morphology and physiology of plants, and follows with the principal peculiarities of the more important classes and genera, special attention being given to cryptogams. A good glossary and index add much to the value of the book.

Consumption: How to prevent it and how to live with it. By N. S. DAVIS, JR., A.M., M.D. Philadelphia and London: F. A. Davis. 1891.

Dr. Davis writes especially for the instruction of consumptive patients. His book is very readable and contains much valuable information in general hygiene, exercise, choice of occupation, climate, etc.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MARCH 17, 1892.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications, for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

INTESTINAL DYSPEPSIA.

THERE is a form of dyspepsia which is predominantly intestinal. Chymification may be normally performed in the stomach (as is shown by the syphon), but the work of the stomach is not properly supplemented by those processes in the small intestines which elaborate the chyle and render it fit for absorption. Every physician in general practice has had cases which correspond to the following description: The patient has little or no trouble with the primary or gastric digestion, but some few hours after meal has attacks of flatulence with abdominal pains of greater or less severity, and this may be followed by diarrhoea.

Eruptions of gas and the expulsion of flatus do not necessarily indicate faulty intestinal digestion, for the trouble may be purely of gastric origin (type—gastric dilatation, gastric neurasthenia), and it sometimes requires the utmost sagacity of the physician to determine in a given case the parts to be assigned respectively to gastric and intestinal indigestion. Often the flatulent distension can be topographically located in coils of the small intestine or in the colon, while the stomach appears to be empty, or, at least, not distended. Gastrectasis can be differentiated by symptoms of its own; and always the use of the stomach syphon is an aid to accurate diagnosis by the certain information which it furnishes as to the quality of the gastric contents.

A peculiarity of intestinal dyspepsia is that it is principally the starchy and saccharine articles of food that give trouble. This might *a priori* be inferred, for the peptonization of albuminoids is effected chiefly in the stomach, which, in the kind of dyspepsia under consideration, is supposed to be in a relatively normal condition. While then it is quite possible that the ingestion of an excess of albuminoids, over-fatiguing the stomach, may cause intestinal embarrassment (and it is also possible that in rare instances exaggeration of the ordinary peristaltic movements may effect the same result, the ingesta being hurried out of the stom-

ach before the work of chymification is half completed), ordinarily and for all practical purposes the name intestinal dyspepsia may be considered as synonymous with starchy or amylaceous dyspepsia.

Is there a "buccal" or "salivary" dyspepsia due to lack of saliva? The relative part to be assigned to saliva in the conversion of starches has not yet been determined; it is doubtless insignificant as compared with that of the intestinal and pancreatic secretions.

The bile, pancreatic juice and the intestinal juice are the influential factors of intestinal digestion. Deficiency or perversion of any one of these fluids may cause indigestion, and it is probable that atony of the intestinal muscle—as a part of general muscular atony—may in some instances have an important rôle in indigestion.

The influence of bile on the intestinal digestion has long been known. Constipation and flatulence generally accompany deficiency or absence of bile; the rapid emaciation that is seen in individuals or animals with biliary fistula also confirms the traditional physiological notion that the bile is an important agent in the emulsification of fats. Functional or organic derangements of the liver, then, may cause intestinal indigestion.

Deficiency or perversion of the pancreatic secretion will seriously derange chylification. The pancreatic juice possesses ferment which act on all the elements of food; albuminoids, carbo-hydrates and fats; the intestinal juices also transform starches and proteids. These are facts which are sufficiently trite; unfortunately it is difficult, if not often impossible in a given case of dyspepsia, whose seat has been referred to the small intestines, to determine to which of the three factors of the intestinal digestive process the cause belongs, or whether all the glandular secretions may not be about equally at fault. There are, it is true, some symptoms which point clearly enough to intestinal atony by acholia; we have, however, no symptoms which indicate with equal clearness failure of function of the intestinal glands or pancreas. But even if we knew the morbid states productive of the digestive disturbances, we should seldom be able to influence these states directly by remedies; in other words, therapeutics must be symptomatic rather than etiological.

The brief hints which we shall give as to treatment will be comprised under the following heads: (1) Dietetics; (2) antiseptics; (3) eueptic remedies; (4) purgatives.

(1) As this form of dyspepsia is generally predominantly a dyspepsia of starches, there is a leading indication to abstain from amylaceous and saccharine articles of diet. There should be a maximum of albuminoids—meat, eggs, fish, and a minimum of carbo-hydrates and fats. Brilliant results have been obtained from a diet of raw meat—six, eight, even ten ounces of lean beef or mutton reduced to a pulp and cooked but slightly, if at all; to be eaten well seasoned, with a little bread, but without vegetables.

Thin slices of underdone roast meat, fresh broiled fish, raw oysters and other shell-fish, soft boiled eggs, boiled ham. The latter, with sour-kraut, smoked herring, a little stale cheese, etc., has been recommended as being especially unlikely to undergo putrefactive decomposition.

There is no doubt that patients who have been the greatest sufferers from flatulence and colic, the result of intestinal indigestion, have often been marvellously benefited by this meat régime. For drinks, dilute soups, broths, watery solutions of the popular meat-extracts, are always preferable to milk, which is too liable to fermentation. Ales and all other fermented liquids are of course to be eschewed. The same may be said of puddings and gruels. If milk is to be prescribed, milk curds (without sugar) are not always objectionable.

Chronic indigestion is generally the result of flagrant dietary errors. The individual has at some time indulged his appetite to excess, and done this habitually; the digestive organs have become overburdened, and functional derangements, if not gross organic lesions, have resulted. Or food of a poor quality and indigestible, has overtaxed the apparatus of digestion. Here the main treatment must still be dietetic — the only indication capable of fulfilment being to give rest to the damaged organs till *restitutio ad integrum* takes place. The patient must be compelled to live sparingly, and on the kinds of food (principally azotized) which will digest best, and give the least trouble.

(2) There is no doubt as to the utility of antiseptic remedies (that is, remedies which prevent and counteract morbid fermentations) in intestinal dyspepsia. Combinations of chalk, bismuth, magnesia, salol, salicylate of soda, aromatics, are often beneficial. The patient may take after each meal a powder consisting of five grains each of prepared chalk, magnesia and salol, or five grains each of salicylate of bismuth and naphthol. The addition to these powders of a little powdered nux vomica or columbo is often beneficial, especially where there is an indication to stimulate sluggish contractility. Turpentine is a remedy which some think has quite a wide range of usefulness.

Are there ever instances where exaggerated peristaltic movements are the principal cause, the ingesta being hurried out of the stomach into the intestines before gastric peptonization is half completed? If such cases could be diagnosticated, there would be a clear indication for opiates and other remedies which diminish peristalsis.

(3) Among the "eueptic" remedies (that is, remedies which favor digestion), must be mentioned, as being of predominant importance in the dyspepsia under consideration, malt-extracts and pancreatin. Malt-extracts contain diastase and are believed to be of benefit in amylaceous dyspepsia; this belief seems to be sanctioned by clinical experience. To be efficacious they should be given with the food.

Pancreatin, or pancreatic extract, has the earnest commendation of Dr. William Roberts in the *British*

Medical Journal. He directs the usual dose (a teaspoonful of the extract, or ten to fifteen grains of purified pancreatin) to be given with fifteen grains of bicarbonate of soda two hours after a meal when intestinal digestion might be supposed to have fairly begun. Gubler recommended pancreatin to be given in capsules of wax, with the expectation that they would pass through the stomach unattacked by the gastric juice and deposit their contents in the duodenum after destruction of the waxy coating. There are various pharmaceutical preparations which profess to contain the three ferments, diastase, pepsin and pancreatin. Some physicians claim to have derived benefit from these combinations; others look upon the pretensions of their proprietors as illusory. These substances, being ferments, easily spoil, nor is their stability always ensured by combining them with alcohol, which more or less modifies their properties.

(4) The utility of purgatives in clearing the intestines of putrefying débris, of gases, ptomaines and microbes is unquestioned, but they are not to be given as a matter of routine, and only when constipation, colic or other symptoms indicate their administration. The relief which often follows a mild cathartic is great. Of course, only the milder laxatives, and such as disturb digestion the least, are to be thought of. Rhubarb, senna, aloes, sulphur, cascara, magnesia are among the best. A favorite combination is equal parts of pulverized rhubarb and cardamom seeds; dose, a teaspoonful. German Séé prefers the old formula of sulphur, cream of tartar and magnesia, of each equal parts; Dujardin-Beaumetz, the compound licorice powder. The aloin, strychnia, belladonna, and ipecac pill is an excellent one.

"The remedy," says Dr. G. B. Wood, "which we have found most effectual in the permanent cure of a disposition to the accumulation of flatus in the bowels, is an infusion made with half an ounce of columbo, half an ounce of ginger, a drachm of senna, and a pint of boiling water, and given in the dose of a wineglassful three times a day.

TREATMENT OF NEURASTHENIA BY TRANSFUSION (HYPODERMIC INJECTION) OF NERVOUS SUBSTANCE.

At a recent meeting of the Paris Academy of Medicine (Session February 16, 1892), Constantin Paul reminded the assembly of the first communication of Brown-Sequard to the Society of Biology on subcutaneous injections of testicular liquid. In a number of instances a profound stimulation, an uplift of all the forces, followed; this lasted a considerable time, and was not followed by a corresponding depression. Constantin Paul compares this effect to what often takes place after injections of nervous substance into the subcutaneous cellular tissue.

The liquid which he used was a ten per cent. solution of the gray matter of a sheep's brain: this was first macerated for twenty-four hours in glycerine wa-

ter, then filtered through Darsonval's carbonic acid filter, which sterilized it. The resulting liquid was absolutely transparent.

M. Paul first injected one cubic centimetre of this liquid under the skin in the lumbar region, and subsequently increased the quantity to five cubic centimetres every third or fourth day, using all the antiseptic precautions necessary. The injection was perfectly tolerated, producing no local or general reaction. Out of more than two hundred injections practised on eleven patients, he failed in any instance to witness any phlegmon or pustule following the injection.

The patients on whom he performed these injections were classed as follows: Four were victims of tabes; one was a case of permanently slow pulse: three were suffering from ordinary neurasthenia; three were neurasthenic chlorotics. There was in all a general tonic effect characterized by increase of strength, appetite and weight, restoration of spirits and *bien-être*, disappearance of pain, sexual impotence and insomnia.

M. Constantin Paul concludes that "injections of the gray cerebral substance constitute a true tonic for the neuropathic." "The neurasthenic," he adds, "is a patient whose nervous system resembles an accumulator which it is impossible to charge. As long as the disease lasts, the neurasthenic eats to no good purpose, for he cannot transform his food into force. On taking the least exercise, the muscular, nervous and other forces are exhausted."

"The injection of nervous substance promotes the utilization of foods and their assimilation. The nervous system becomes a condenser which can be charged, and the patient acquires a quantum of forces which he can dispose of at his will. But the nervous force is the first to develop, and this leads to the development of the other forces, and the ability to do work of the muscles and brain."

Great expectations may certainly be entertained of this mode of treatment, if one is prepared to believe, as Dr. Paul affirms, that "the injections ameliorate and cure the neurasthenic and enfeebled more rapidly than the ordinary agents of the *materia medica*, iron, arsenic, phosphates, opium and alcohol," and if "their action is more rapid and more certain than that of hygiene alone, of hypnotic suggestion, and of electricity!"

MEDICAL NOTES.

CENSUS OF NEW YORK CITY.—The returns from the State census for New York city, recently completed, not including inmates of public institutions, gives the city 1,890,891 inhabitants. The Federal census of 1890 showed a population of 1,515,501.

ELECTROCUTION IN DANGER.—The New York State Assembly Committee on Codes has agreed to report favorably the bill amending the capital punishment act of the State. The bill does away with the electrical chair and substitutes hanging.

TYPHUS FEVER IN PHILADELPHIA.—Two cases of typhus fever are reported from Philadelphia. The patients are sisters, one of whom had recently arrived from New York, where she was said to have been a nurse in Bellevue Hospital.

UNIVERSITY CHANGES.—The Chair of Obstetrics in the Medico-Chirurgical College of Philadelphia, has become vacant through the resignation of Dr. F. E. Montgomery, who will hereafter devote himself entirely to the Chair of Gynecology. Dr. William G. Anderson, Director of the Brooklyn Normal School of Physical Education, has been appointed physical instructor at Yale.

THE INTERNATIONAL MEDICAL MAGAZINE.—The first number of a new medical monthly with the above title has just appeared. It is edited by Judson Daland, M.D., and published by the J. B. Lippincott Company. Each number is to contain more than a hundred pages, and is to include original contributions, clinical lectures and reviews of recent medical publications. The first issue contains much interesting and valuable reading.

THE NEW YORK STUDENT RELIEF BILL.—There appears to be danger that the value of the new law in New York requiring examination in order to obtain a license to practise medicine, may be diminished by a bill which has been introduced to relieve several medical students from the necessity of passing the State medical examination. There appears to be no reason why these students should be exempt; and if it is possible to enact similar laws yearly, the value of the original law will be very much diminished.

TO EXAMINE RUSSIAN EMIGRANTS.—The Hamburg-American Packet Company, in conjunction with the Prussian authorities, has arranged that all Russian emigrants intending to come to the United States in the Hamburg-American steamers shall be inspected before entering Prussia. Any of these Russians who are suspected of being infected with typhus fever or other diseases will not be allowed to enter the country. All the emigrants' lodgings in Hamburg will be carefully supervised, and another examination will be made by two physicians under the direction of the United States Consul at Hamburg, before the emigrants are permitted to embark upon the steamers.

TUBERCULOSIS IN BUDA-PESTH.—Professor Fodor shows that Buda-Pesth has the greatest relative mortality from tuberculosis of any large city in the world. There are about 600 deaths from this cause in each hundred thousand inhabitants yearly, whereas in Vienna there are about 550 and in London less than 200. He considers that the bad pavement and insufficient street-cleaning have much to do with this large mortality.

VIENNA GENERAL HOSPITAL.—The Austrian Parliament has been considering the advisability of enlarging this already gigantic institution. There is no doubt that most of the buildings now in use are not up to modern standards of hospital construction. It is

proposed to add to the institution the military barracks which now adjoin it.

LECTURES OF THE ROYAL COLLEGE OF PHYSICIANS, LONDON.—The series of lectures for the present year are as follows:—*Mirroy*: by Dr. Francis Warner, "On the Physical and Mental Condition of School Children." *Goulstonian*: Dr. Sidney Martin, "On the Chemical Pathology of Diphtheria, compared with that of Anthrax, Infective Endocarditis, and Tetanus." *Lumleian*, Dr. Pye-Smith, "On Certain Points in the Etiology of Disease."

MEMORIAL TO SIR MORELL MACKENZIE.—Lord Calthorpe, who has had charge of the fund for the erection of a memorial to the late Sir Morell Mackenzie, has announced that the fund will be devoted to the erection of a permanent addition to the Hospital for Diseases of the Throat, which was founded by Dr. Mackenzie in 1864, and with which he was connected until the time of his death.

DIPHTHERIA IN DIFFERENT COUNTRIES.—The Chief of the Bureau of Medical Statistics of Brussels gives the following as the number of deaths from diphtheria in the principal countries of the world, per one thousand inhabitants: England 41, Belgium 44, Holland 53, Switzerland 59, Italy 79, France 80, Germany 100, Scandinavia 110, Spain 112, Austria-Hungary 116, America 140.

THE MILITARY STEP AND ITS PHYSICAL EFFECTS.—A French army surgeon has been making some investigations, says the *Medical Press*, into the physical effects of the military step upon armies on the march. He affirms that the regularity of the step causes the indefinite repetition of a shock to the bones and the brain, infinitely more deleterious than an irregular walk, and to this regular repetition of the shock to the same parts of the body is due the peculiar aches, pains, and sickness among the troops. In a one-day march this shock is repeated 40,000 times, and often the strongest men, who can walk the same distance without difficulty when not in line, succumb to the strain in two or three days. With regard to the remedy, the author suggests the insertion of a rubber heel in all military boots. The heel has been tried at his instance in the French infantry, and the result has been found to afford great relief to the men. The experiments with the rubber heel are still in progress, so that in time we may look for further facts in connection with this subject.

THE HEALTH OF THE SURVIVORS OF THE WAR.—In a recent number of the *Forum* Dr. John S. Billings endeavors to show the effect of military service upon the health of the men in the two armies. Although a large number of men were more or less seriously affected by their services in the field, there were undoubtedly some who derived benefit from the life in the open air and regular exercise. The average death-rate since the close of the war has been between thirteen and fourteen per thousand. It would seem that the average death-rate of the survivors of the war for

the past twenty years has been a little higher than that of the average population of males of the same age. In the State of Massachusetts, according to available statistics, he finds that the proportion of sick men is at least four times greater among veterans than it is among other males of the same age. It would seem, therefore, from the figures which he used that the health of the veteran, in this State at least, was unfavorably influenced by his service. This conclusion is, however, only provisional, and does not seem to accord with his personal opinion derived from contact with a large number of surviving veterans. Statistics are so meagre that it is impossible to arrive at a definite conclusion on this subject.

BOSTON AND NEW ENGLAND.

THE WEST END NURSERY AND INFANTS' HOSPITAL.—The ninth annual report of this institution shows that during the year fifty-four children were cared for in the nursery department and forty in the hospital. Eighteen mothers were admitted.

BIRTHS IN BOSTON.—From the tables recently issued by the acting registrar, it appears that in Boston during the year 1891 the total number of births was 14,206, of which 7,292 were males, and 6,914 females. The daily average was 39.05. There were 245 colored births, of which 109 were male and 136 female. There were 142 pairs of twins, and four sets of triplets. There were two Chinese children born, one male and the other female.

A CREMATORIUM IN BOSTON.—Arrangements have been completed for the transfer of the control of the Worcester Cremation Society to Boston. The company is duly incorporated under State laws and has a capital of \$25,000. It is said that 150 stock subscriptions have been made in Boston, and that a lot will be purchased and a crematory erected. The following are the officers: Clerk, Dr. John Homans, 2nd; treasurer, John Ritchie; directors, Dr. James R. Chadwick, Dr. Henry P. Bowditch, Augustus Hemenway, Russell Sturgis, Jr., and Babson S. Ladd, all of Boston; Stephen Salisbury and Dr. J. O. Marble of Worcester. There are also two women on the directorate.

MASSACHUSETTS LEGISLATURE.—In the House the cigarette bill was amended so that the manufacture and sale of those cigarettes only is forbidden which are wrapped in paper covers. The prohibition seems now to be reduced so as to apply only to the smoking of paper. The bill was laid over until this week. The Committee on Public Charitable Institutions has reported a resolve to appropriate for the Massachusetts Charitable Eye and Ear Infirmary, and has reported leave to withdraw on the petition for the appointment of a woman on the Board of Public Institutions in Boston.

MARINE HOSPITAL ON MARTHA'S VINEYARD.—The Government has accepted six acres of land at Vineyard Haven as the site of the new Marine Hospital. The tract is situated on the bluff across the harbor from the village of Vineyard Haven.

NEW YORK.

TYPHUS FEVER.—Up to March 10th there were reported 153 cases of typhus fever, among which there were 13 deaths; two of the deaths being among the attendants on the sick in the hospital. At that date there were at North Brother Island 82 typhus patients and about 80 quarantined individuals who had been exposed to the infection of typhus. On the following day there were two additional deaths and three new cases reported. The Board of Health has engaged in an investigation of the hospital at North Brother Island, serious charges having been made as to the manner in which patients were treated there.

BEQUESTS TO INSTITUTIONS.—By the will of Major-General George W. Cullum, recently deceased, \$6,000 is left to the Woman's Hospital and \$10,000 to the New York Cancer Hospital, which the wife of Gen. Cullum had liberally endowed.

TRAINING SCHOOL FOR MALE NURSES.—The graduating exercises of the Bellevue Hospital Training School for Male Nurses took place on the evening of March 9th. The Training School for Male Nurses was opened for the reception of pupil nurses on December 17, 1888. In 1891 the school graduated eighteen nurses. This year there are seventeen graduates. There have been 698 applications for admission, 166 probations have been accepted, and there are now 56 pupil nurses on the rolls.

—
Miscellany.

THE PADDOCK BILL FOR PURE FOOD AND DRUGS.

The Paddock Pure-Food bill as recently passed by the Senate provides for the organization, in the Department of Agriculture, of a section, to be known as the food section of the chemical division, whose duty it shall be to analyze, or cause to be analyzed or examined, samples of food or drugs offered for sale in any State or Territory other than where manufactured, or in any foreign country, provided they be in original and unbroken packages. It prohibits the introduction into any State or Territory, from any other State or Territory or foreign country, of any article of food or drugs that is adulterated or misbranded, and makes the act of doing so a misdemeanor, punishable by a fine not exceeding \$200 for the first offence and not exceeding \$300 for each subsequent offence, and by imprisonment for one year.

The term "drug," as used in the act, is to include all medicines for internal or external use. The term "food" is to include all articles used for food or drink by man, whether simple, mixed, or compound. Drugs are to be considered adulterated when they differ from the standard of strength, quality, or purity recognized in the United States Pharmacopœia or other standard works, or when in imitation of and sold under the specific name of another article; when mixed, colored, powdered, or stained so as to deceive the purchaser; when poisonous or injurious ingredients are added;

when the article consists, in whole or in part, of a diseased, filthy, decomposed, or putrid animal or vegetable substance, or any portion of an animal unfit for food.

Articles of food or drugs that do not contain any poisonous ingredient shall not be deemed to be adulterated in the case of mixture or compounds under distinctive names; or in the case of articles labelled, branded, or tagged so as to indicate plainly that they are mixtures, compounds, combinations, or blends; or when any matter is added so as to fit the article for carriage or consumption and not to increase its bulk fraudulently or to conceal its inferior quality; or where the food or drug is unavoidably mixed with some extraneous matter in the process of collection or preparation.

Every person who manufactures for shipment and delivers for transportation, from any State or Territory to any other State or Territory, any drug or article of food, and every person who exposes such articles for sale, is required to furnish samples to agents of the Secretary of Agriculture. A refusal to do so is punishable by a fine not exceeding \$100 and not less than \$10, or by imprisonment from 30 to 100 days, or both.

The manufacturer or seller (knowingly) of adulterated, impure, or misbranded articles of food shall, in addition to those penalties, be adjudged to pay all the necessary costs and expenses of inspection and analysis.

The act is not to be construed to interfere with commerce wholly internal in any State or with the exercise of police powers by the States. Adulterated articles transported or being transported from one State to another for sale, and still in unbroken packages, may be proceeded against in the United States District Court by a process of libel for condemnation and may be sold and the proceeds paid into the Treasury.

THE TREATMENT OF THE CRIMINAL INSANE.

At a meeting of the New York Medico-Legal Society, March 9th, Mr. J. T. Graham, of Virginia, read a paper entitled, "What should be Done with Criminals who are Acquitted for Crimes on the Charge of Insanity?" He contended that the number of prisoners released on the plea of insanity was increasing at such an alarming rate that the country was being overrun with the impostors who only feigned insanity at their trial, and with persons who were really insane and were dangerous to the community. He proposed that every person who was guilty of murder, but who was adjudged insane, should be compelled to remain in an asylum for at least ten years. If, during the last five years of this term of confinement they should show no signs of insanity, they should be released. If they did, however, display any symptoms of insanity, they should not be allowed their freedom until five years after such symptoms ceased.

After some discussion of the paper by others, Judge A. L. Palmer, of St. John, spoke of the manner in which such persons were treated in the Dominion of Canada. He said that if a criminal were adjudged insane in the courts, he was incarcerated in an asylum, and was kept there until the Governor-General was pleased to release him. If, after some time, the prisoner was considered of sane mind by those in charge of him, the Governor-General appointed a commission of experts to examine into the case, and if it were re-

ported that the prisoner would not be likely to endanger society on account of his mental condition, the Governor-General would, if he saw fit, release him.

THE WATER-BED AS A MEANS OF AFFECTING THE TEMPERATURE OF THE BODY.

Dr. H. C. Wood¹ calls attention to the water-bed as a means of heating the human body during collapse and cooling it during fever.

In cases of collapse and subnormal temperature occurring during advanced stage of typhoid fever, the severer forms of bronchitis, etc., he has been accustomed to employ an india-rubber water-bed, about half the width of the ordinary mattress. It is placed upon the bed, alongside the patient, partially filled with water at a temperature of 140° to 150° F., and covered with blankets, upon which the patient is laid. The weight of the body carries it down and forces the water up at the sides, so that the person is partially surrounded by the heated water. The mass of the water, and the protection of the blankets, prevent the loss of heat, so that the mattress keeps hot for many hours. When the heat of the body has reached 98.5° F., the patient may be lifted off and laid alongside of the water-bed, which being covered by the same blankets as are over him will keep the temperature up to the normal.

The success in heating the body with this contrivance suggests that the water-bed may also be used instead of the cold bath for reducing temperature. All that would be necessary would be to have the water-bed supplied with two nozzles, instead of the ordinary aperture, and an india-rubber tubing or hose fastened to each nozzle, connecting the one with the spigot, the other with the outlet of the neighboring bathtub or stationary washstand. In this way, without labor or trouble, water of a constant temperature of 40° to 50° F., at least in winter, could be kept in the bed, and it would be very easy to run the water through ice if it were necessary to get further lowering of the temperature.

BANANA FLOUR.

In the *Scientific American* for October 10th, mention is made of the need of a flour for domestic purposes made from the banana.² The author of the article estimates that in Jamaica alone, from whence about one-third of our banana supply comes, the waste in the fruit amounts to several hundreds of thousand bunches per annum, and this, too, with less than one-tenth of the available fruit-producing land under cultivation.

Undersized or undeveloped bunches are rigorously cast out by the buyers, and at many ports these may be had for the asking or at a merely nominal price.

von Humboldt has estimated that thirty-three pounds of wheat, or ninety-nine pounds of potatoes require as great a space for their production as do 4,000 pounds of bananas; and that three good bananas contain as much nutriment as does a fourteen-ounce loaf of bread.

While this "bread of the tropics" will withstand the amount of handling necessary to transportation to our northern markets, by means of our rapid freight delivery systems, it will not withstand a much longer

series of shipments. At present the finest flavored bananas are almost unknown in northern Europe, not because the fruit is unappreciated, but because after transportation to those countries the fruit is in an unmarketable condition. So that from this reason two lines of inventions are sorely needed in the West Indies having to do with banana culture. With these the banana output would soon be doubled, and in time might easily be increased tenfold. These two needed inventions are a dessicating and a flour or meal making process. The former is at present more in demand, so that in those regions the traveller hears the cry continually on every large plantation, "Oh! if some one would only invent and perfect a drying or preserving process that could be depended upon."

The man or men who can put before the banana growers of the West Indies, who annually sent to the United States \$4,000,000 worth of the fruit, any system which will do for the banana what is now done for the fig, grape, or the dried currant, or who can succeed in treating the fruit as well as peaches, apricots, or prunelles now are, will be the possessor of a wealth-producing invention. And the same may safely be predicted of the system that will succeed in putting into the meal or flour a fair portion of the marvellous sustaining and nourishing powers which make the banana the king among fruits.

THERAPEUTIC NOTES.

HYDRASTININ. — Strassmann¹ presents a paper upon this drug, which is to be distinguished from hydrastin. The dose is: in form of pill, one-half grain; in subcutaneous injection, one to two grains. The results of administration in twenty-seven cases lead him to believe it to be a very valuable remedy in the menorrhagias and metrorrhagias due to various pathological conditions so often met with in gynaecological practice. At present, however, the remedy is quite expensive.

BANANAS IN CHRONIC BRONCHITIS. — For chronic bronchitis with scanty expectoration the use of banana-juice has been recommended.² The juice is prepared by cutting up the bananas in small pieces, and putting them, with plenty of sugar, in a closed glass jar. The latter is then placed in cold water, which is gradually made to boil. When the boiling point is reached, the process is complete. Of the syrup so made, a teaspoonful every hour is the proper dose.

ACETANILID FOR THE PRESERVATION OF SOLUTIONS. — Keenan³ recommends the addition of a small amount of acetanilid to solutions of alkaloids to prevent fungoid growths.

THE ADMINISTRATION OF CHLOROFORM. — Gisevius⁴ describes a method of administering chloroform by the drop-by-drop method which has been used by several surgeons in Europe.⁵ This consists of giving the chloroform in drops only, continuing for five or ten minutes until the patient is completely narcotised. The advantages of this method are, absence of the reflexes proceeding from the mucous membranes, the

² Sanitarian, February.

absence of the stage of excitement and the small amount of chloroform necessary. At the Augusta Hospital no case of cardiac syncope or failure of respiration have occurred since the method was introduced.

With regard to the pure chloroform of Pictet, Bardeleben finds that it acts more quickly and in a milder manner than the old, and that less is required. Koite, however, had had a death from the purified drug in a healthy patient. This case strengthened his belief that deaths from chloroform were not, as a rule, due to any impurity in the drug used, but to the individual characteristics of the patient. Hahn gave chloroform by gradual droppings; the anesthesia was very satisfactory, even in drinkers. He let about sixty drops per minute fall from an ordinary drop bottle upon the mask.

Correspondence.

LETTER FROM JAPAN.

YOKOHAMA, February 9, 1892.

MR. EDITOR:—The Central Board of Health for Japan operates in the capital, Tokyo, under control of the general government. It is composed of physicians, chemists, jurists and other officials. This board is an advisory council for the executive authorities. Its officers go to various parts of the empire for sanitary inspection and supervision. In each of the forty-five Ken (or provinces) of the country, is a local Board of Health of similar construction and functions, with analogous relations to the local government.

There is also a parallel organization known as "The Sanitary Association," which has the approval of the government, but no formal official recognition. Its work supplements that of the Board already mentioned: such voluntary assistance is especially valuable during epidemics. This society publishes a monthly "Journal" in the Japanese language. This publication has about fifty pages (12mo); several articles are accompanied by cuts showing plans of contemplated works, and forms of apparatus. A large number of different subjects more or less directly connected with sanitation are discussed in each issue.

A recent number of the *Sei-ka* (Medical Journal) contains some interesting matter republished as follows in the *Japan Mail*:—Dr. J. Sakaki contributes a paper containing the results of experiments carried on by him to determine whether rice in certain conditions has any poisonous properties. These experiments seem to have been suggested by an idea that possibly *kakke*, that disease so serious in Japan, might be due to rice-poisoning. Dr. Sakaki began his investigations in 1888. He tells us very simply that, finding the intervals of his regular work insufficient for the purpose, he resigned his position in the Imperial University, and devoted himself wholly to experimenting. He commenced by examining the fungi found on ears of rice, and then he passed to "red rice," that is to say, rice that had changed its color during cultivation. But the results obtained in these cases were negative. Success attended him, however, on proceeding to examine mouldy rice, commonly called *sawate-mai*. Mouldiness in rice is caused by rain, when it is called *umore-sawate*; or by simple moisture, when it is *fuke-mai*; or by some unexplained local influence, when it is called *mosu-mai*. It appears in the form of yellowish gray spots, and Dr. Sakaki speaks of grains thus marked being mixed with the rice eaten every-day by Japanese. He made various investigations to determine how the spots were produced, but the results are not yet published, though he foresees that they will be of practical value in respect to the storing of grain. There seems to have been considerable difficulty in extracting the supposed alkaloid poison from the rice, 2,500 grammes of mouldy rice giving only 0,299 gramme of the alkaloid, but the tests made with the

latter upon frogs and rabbits go to prove very clearly Dr. Sakaki's conclusions, namely, that mouldy rice contains a small quantity of poisonous principles, which act slowly, on the nerve centres for the most part, and the chemical composition of which is as yet unknown.

Dr. Kusaka's paper, originally published in the *Official Gazette*, discusses that very interesting and often referred to question, whether flies assist to propagate epidemic diseases. Our readers probably remember the newspaper accounts of a panic caused in an American town last year by the suggestion that mosquitoes could carry poison from a Chinese leper throughout the whole community. Dr. Kusaka's researches go to prove that there was good reason for the scare. His experiments show that cholera bacilli, for example, may find a congenital nutritious fluid in a fly's abdomen, and may thus be transported from an infected place to the food which a healthy person is about to eat. This fact will furnish another argument to persons who maintain the uselessness of quarantine and other means of isolating sufferers from infectious diseases."

The number of cases of small-pox officially reported in Tokyo on the 30th and 31st of January was 102. During last month 1,073 persons were affected, with 272 recoveries and 91 deaths. The disease appears to be abating in Yokohama, the number of new cases reported being about ten daily. 80,000 persons have been vaccinated by the authorities during the prevalence of variola. The population of this city was 139,045, December 31, 1891.

Very respectfully, F. B. STEPHENSON,
Surgeon, U. S. N.

A NEW, SAFE AND SURE METHOD OF EXPEDITING DIFFICULT CASES OF LABOR.

ALLSTON, MASS., March 3, 1892.

MR. EDITOR:—A correspondent, in your issue of February 25th, refers to my remarks February 4th on "A New, Safe, and Sure Method of Expediting Difficult Cases of Labor." Dr. Playfair, of London, in speaking of this modern oxytocic, says: "I am satisfied we have in it a most valuable addition to our resources, which is as yet not sufficiently appreciated, and which is destined to take a recognized place . . . in every way safer and more manageable than ergot." He also says, "I have never seen anything which led me to think that with due care, it has had any sort of injurious effect."

In the *Illustrated Encyclopedia of the Science and Practice of Obstetrics* (p. 150, ¶ 7), published in 1883, one year after my article was read before the Gynecological Society of Boston, the writer says, referring to this method: "It has the peculiar advantage of closely imitating the natural means of delivery, and of being absolutely without risk to the child. Nor is there any reason to think that it is capable of injuring the mother; . . . as its application is always intermittent, there is no time for it to inflict any injury on the uterine tissues." My eighteen years' practice and use of this method proves to me its perfect safety when intelligently used. It would seem, that the above evidence was satisfactory as to the safety of the method.

As to its being new: from time immemorial, by certain wild tribes of men, as in some civilized countries in modern times, assistance has been rendered women in labor in some manner, somehow, by pressure applied by various means, as well as by the hands of the accoucheur directly applied upon the abdomen, but not always safely or in an intelligent manner. The method, as formulated in my article, giving explicit directions how, and when, pressure should be applied, and the precautions relative to its use and application, was certainly new.

I do, most decidedly, take exception to the statement of your correspondent, "but all things were natural," in the patient he alludes to, she having taken ergot in the first stage of labor and been subjected to its physiological action, — a tonic contraction of all the muscles of the uterus until their complete exhaustion, — and there continuing a condition

of complete inertia of the womb for twelve hours or more, the child still unborn; for neither the patient nor the child under those conditions could be in a natural condition.

A practitioner giving ergot as above, with such results, would be guilty of the grossest malpractice; for if you induce the physiological action of ergot on the womb, in a case as cited above, and the child is not born within an hour of the commencement of such action (the tonic contraction continuing), you will invariably have a dead child as a result of such a use of ergot. Such a practitioner would not be using the ordinary care or skill in the practice of the obstetric art which the law requires.

I do not believe that it was possible for the intermittent pains of labor, with the pressure applied intermittently as claimed (without some other attending circumstance) to produce strangulation of the cord and death of the child; certainly not, before it had entered or passed the upper strait.

We very much doubt that the consensus of opinion of obstetricians of to-day would advise venesection, in the average woman in labor under like conditions as in the case cited, to the extent of overcoming the rigidity of the unyielding os, when a few doses of chloral hydrate would speedily and safely overcome the rigidity, leaving the patient in a more natural condition and without the shock and excitement and the anæmia which would be induced by the venesection.

Yours very truly.
MARSHALL L. BROWN, M.D.

"KEEN'S OPERATION" FOR SPASMODIC TETRICOLOSS DUE TO IMPLICATION OF THE POSTERIOR ROTATORS.

35 W. 35TH STREET,
NEW YORK, March 8, 1892.

MR. EDITOR:—Your issue for January 7th, current year, contains a stenographer's report of the proceedings of the New York Neurological Society, in which report mention is made of a case of wry-neck operated upon by me. Reference to the complete paper, *New York Medical Journal*, March 5, 1892, will show that full credit for priority in conception, execution and publication of the operation as done by me is, and should be, accorded to Dr. W. W. Keen of Philadelphia. I feel that the procedure is one of much value,—one which will be of use and of necessity in intractable cases of wry-neck due to spasm of the posterior rotators,—and I am sure that you will be glad to place before your readers the credit which is due Dr. Keen for his original and painstaking work.

Very truly yours,

CHARLES A. POWERS, M.D.

METEOROLOGICAL RECORD.

For the week ending March 5, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 2,937: under five years of age 1,041: principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fever) 384; acute lung diseases 289; consumption 361; diphtheria and croup 152; scarlet fever 87; diarrhoeal diseases 56; typhoid fever 32; diphtheria 21; cerebro-spinal meningitis 17; erysipelas 14; whooping-cough 11; malaria 10; typhus 4; tularemia 2; puerperal fever 2; small-pox (New York) 1.

From typhoid fever Philadelphia 14, Pittsburgh 6, New York and Lowell 3 each; Boston, Cincinnati, Washington, Fall River, Lawrence and Haverhill 1 each. From measles New York 14, Brooklyn 3, Philadelphia 2, Pittsburgh and Worcester 1 each. From cerebro-spinal meningitis New York 7, Brooklyn, St. Louis and Washington 2 each; Philadelphia, Nashville, Lowell and Malden 1 each. From erysipelas New York 8, Cincinnati 3, Brooklyn, Washington and Northampton 1 each. From whooping-cough New York 3, Fall River, Cambridge, Gloucester and Medford 1 each. From malarial fever Brooklyn 3, New York 1. From typhus fever New York 2. From puerperal fever Boston and Cambridge 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,185,736, for the week ending February 27th, the death-rate was 23.4. Deaths reported 4,571: acute diseases of the respiratory organs (London) 461; whooping-cough 155; measles 123; diphtheria 49; diarrhoea 39; scarlet fever 31; small-pox (Liverpool) 1.

The death-rates ranged from 14.2 in Croydon to 34.0 in Bury; Birmingham 23.6, Bradford 19.7, Hull 18.3, Leeds 21.4, Leicester 21.5, Liverpool 29.6, London 22.4, Manchester 25.0, Nottingham 27.4, Plymouth 23.1, Sheffield 21.7, West Ham 18.6, Wolverhampton 25.0.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 5, 1892, TO MARCH 11, 1892.

MAJOR ALFRED A. WOODHULL, surgeon, U. S. A., having completed the duties assigned him by Par. 4, S. O. 303, A. G. O., December 30, 1891, will proceed from New York City, N. Y., to Hot Springs, Arkansas, and take station thereat as surgeon in charge of the Army and Navy General Hospital.

March 9, 1892. By direction of the President, the retirement

from active service this date, by operation of law, of COLONEL **BASIL NORRIS**, surgeon, U. S. A., is announced.

FIRST-LIEUT. PHILIP G. WALES, assistant surgeon, U. S. A., is relieved from further duty at Fort Apache, Arizona, and will report in person to the commanding officer, Fort Bowie, Arizona Territory, for duty at that station, relieving **FIRST-LIEUT.** WILLIAM N. SUTER, assistant surgeon, U. S. A.

A board of medical officers to consist of **MAJOR DAVID L. HUNTINGTON**, surgeon; **CAPTAIN HENRY S. TURBILL**, assistant surgeon; **CAPTAIN HENRY S. KILBOURNE**, assistant surgeon; **CAPTAIN WALTER W. R. FISHER**, assistant surgeon, is constituted to meet in New York City, on the 1st day of April, 1892, or as soon thereafter as practicable, for the examination of candidates for admission to the medical corps of the Army.

CAPTAIN MARLBOROUGH C. WYETH, assistant surgeon, U. S. A., is relieved from further duty at Fort McIntosh, Texas, and ordered to Fort Supply, Indian Territory, upon the expiration of his present sick leave of absence.

CAPTAIN JEFFERSON R. KEAN, assistant surgeon, U. S. A., is relieved from duty at Fort Robinson, Neb., and ordered to St. Francis Barracks, Mo., for duty, not later than March 25, 1892, relieving **MAJOR DAVID L. HUNTINGTON**, surgeon, U. S. A. Major Huntington, upon being relieved by Captain Kean, will proceed to New York City, for duty in connection with the Army Medical Board.

CAPTAIN MARCUS E. TAYLOR, assistant surgeon, U. S. A., granted leave of absence for six months, on surgeon's certificate of disability.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 12, 1892.

F. B. BRAITHWAITE, assistant surgeon, from Marine Hospital, Chelsea, and to the U. S. S. "Fern."

M. F. GATES, assistant surgeon, from the U. S. S. "Fern" and granted two months' leave.

HENRY LA MOTTE, assistant surgeon, ordered to the U. S. Receiving-ship "Vermont," at New York.

L. L. VON WEDEKIND, assistant surgeon, from the U. S. S. "Vermont," and granted three months' leave.

EDW. KERSHNER, medical inspector, orders to the U. S. S. "San Francisco" revoked.

WM. K. VAN REYSEN, medical inspector, detached as assistant to Bureau, Medical and Surgical, and to the U. S. S. "San Francisco."

J. D. GATEWOOD, passed assistant surgeon, ordered to the U. S. S. "Dolphin."

E. R. STILT, assistant surgeon, ordered to the Naval Hospital, Philadelphia, Pa.

INTERNATIONAL PERIODICAL CONGRESS OF GYNECOLOGY AND OBSTETRICS.

The Belgian Society of Gynecology and Obstetrics, under the patronage of the Belgian Government, has taken the initiative in organizing "The International Periodical Congress of Gynecology and Obstetrics," the first session of which will be held in Brussels, September 14 to 19 inclusive, 1892.

Three leading questions will be offered for discussion: (1) "Pelvic Suppurations"; Referee, Dr. Paul Segond, Paris. (2) "Extra-Uterine Pregnancy"; Referee, Dr. A. Martin, Berlin. (3) "Placental Praevia"; Referee, Dr. Berry Hart, Edinburgh.

Fees. — Members participating in first session, 30 francs. (This will entitle the holder to a copy of the proceedings of the Congress.) Foreign (life-membership), 300 francs.

In connection with the Congress there will be an International Exhibition of Instruments and Appliances pertaining to Gynecology and Obstetrics.

All communications pertaining to this Congress should be mailed direct to the American Secretary, who will promptly furnish all information. All notifications to be forwarded should be received by August 1st.

DR. JACOBS, *Secretary General*,
12 Rue Des Petits-Carmes, Bruxelles.
DR. F. HENROTIN, *American Secretary*,
334 La Salle Ave., Chicago.

ELEVENTH INTERNATIONAL MEDICAL CONGRESS ROME, 1892.

The Tenth International Medical Congress, meeting at Berlin in 1890, appointed, when closing the session, Rome as the seat of the Congress in 1893, and Rudolf Virchow, consigning the standard of the presidency to Prof. Guido Bacelli, formed his best wishes for the next meeting of so many illustrious men of science.

The presidents of the Medical Faculties, of the Universities and scientific institutions, together with the most prominent

personalities of the Italian medical body, united in Rome in order to establish the basis of the future *Eleventh International Medical Congress*, and proclaimed by acclamation the Hon. Guido Bacelli, President General; Prof. Edvardo Maragliano, clinical physician in Genoa, was elected Secretary General; Comte Prof. Pagliani, Director General for Public Health in Italy, Treasurer, and Comm. Ferrando, chief of department at the Ministry for Public Instruction, Manager. At the same time were elected by acclamation the following committees of the four main sections corresponding with the following division of the scientific works of the Congress: (1) Anatomy; (2) Physiology; (3) Medical Clinic; (4) Gynecology; (5) G.I. Pathology and Anatomical Pathology; (6) Pharmacy; (7) Surgery and Orthopedics; (8) Psychiatry and Neuropathology; (9) Ophthalmology; (10) Dermosiphilopatology; (11) Legal Medicine; (12) Hygiene; (13) Laryngology and Otology; (14) Military Medicine and Surgery.

The Central Committee has lately elected the foreign committees for the purpose of inviting every nation in the world to adhere to the scope, so that the Congress may turn out worthy of the former ones and add to them what will give the honour of sheltering it. This time, till now chosen for the convection of the Congress, is the month of September, a period when the capital offers a very fine and splendid climate to all its fascinating attractions.

All preparations proceed with promptness and give assurance of a grand and perfect success.

PROF. E. MARAGLIANO, *Secretary General*, Genoa, Italy.

PROF. GUIDO BACELLI, *President General*.

RECENT DEATHS.

SAMUEL LAWRENCE MOORE, M.D., M.M.S.S., died in Boston, March 13, 1892, aged fifty-six years.

BOOKS AND PAMPHLETS RECEIVED.

Ninth Annual Report of the West-End Nursery and Infants' Hospital. Boston. 1892.

Two Addresses upon the late Joseph Leidy, M.D., I.L.D. By William Hunt, M.D. 1891.

Fourteenth Annual Report of the Board of Health of the City of Lowell, for the Year 1891.

Fourteenth Annual Report of the Presbyterian Eye, Ear and Throat Charity Hospital, Baltimore. 1891.

A System of Practical Therapeutics. Edited by Hobart Amory Hale, M.D., assisted by Walter Chrystie, M.D. Volume II. Philadelphia: Lea Brothers & Co. 1892.

Prescribing and Treatment in the Diseases of Infants and Children. By Philip E. Musket, late Surgeon to the Sydney Hospital. Philadelphia: P. Blakiston, Son & Co. 1891.

A Quarter of a Century's Retrospect of Laryngology. By Lennox Browne, F.R.C.S., Ed., President of the British Laryngological and Rhinological Association. London. Reprint. 1892.

Cure Radicale de la Hernie Sans Etranglement Chez La Femme. Par Le Dr. Just Lucas-Championniere, Chirurgie de l'hôpital Saint-Louis. Paris: Alex. Cooz, Libraire-Éditeur. 1891.

Surgical Diseases of the Ovaries and Fallopian Tubes, including Tubal Pregnancy. By J. Bland Sutton, F.R.C.S., assistant Surgeon to the Middlesex Hospital, London. Philadelphia: Lea Brothers & Co. 1892.

Memorial: Embodiment Reasons why the Asylum for Insane Criminals, at Auburn, should not be made a receptacle for the Non-Criminal Insane. By Wm. F. Letchworth, Commissioner of the State Board of Charities. Buffalo. 1892.

Diagnosis of the Throat, Nose and Ear. A Clinical Manual for Students and Practitioners. By P. J. McLean, M.D., F.R.C.P., Surgeon to the Ear and Throat Department of the Royal Infirmary, Edinburgh. Philadelphia: W. Blakiston, Son & Co. 1892.

The Mediterranean Shores of America: or, The Climate, Physical, and Meteorological Conditions of Southern California. By P. O. Remondino, M.D., Member of the State Board of Health of California. Illustrated with forty-five engravings and two double-page maps. Philadelphia: F. A. Davis & Co. 1892.

A Dictionary of Treatment or Therapeutic Index, including Medical and Surgical Therapeutics. By William White, M.D., Professor of Materia Medica and Therapeutics in the Queen's College, Belfast, etc. Revised and adapted to the Pharmacopeia of the United States. Philadelphia: Lea Brothers & Co. 1892.

A Practical Manual of Diseases of the Skin. By George H. Robe, M.D., formerly Professor of Dermatology in the College of Physicians and Surgeons, Baltimore, etc., assisted by J. Williams Lord, A.B., M.D., Lecturer on Dermatology and Bandaging in the College of Physicians and Surgeons. No. 13 in the Physicians' and Students' Ready-Reference Series. Philadelphia: F. A. Davis & Co. 1892.

CONDITION OF THE BLOOD IN CERTAIN MENTAL STATES.

BY S. G. WEBBER, M.D., BOSTON.

THE following cases of mental depression, of greater or less severity, in which the blood-corpuscles were counted, are of much interest. The patients were treated at the Adams Nervine Asylum. The first two cases were the severest, both were sent away on account of the amount of depression. In them the blood was poor in red corpuscles, which were also deformed, resembling in this respect the blood of pernicious anaemia. The other cases were less serious and the blood was in a more healthy condition, yet not quite up to the normal standard, except in two cases of dyspepsia.

It may be a question as to how much the mental depression affected the blood, or whether the poor blood was one factor in causing the depression. I believe the latter is the correct statement of the sequence of events.

CASE I. Miss C. E., age thirty-eight, was at one time melancholic, with suicidal tendency. The family history is bad nervously, there being insanity and eccentricity in the family. The patient has been somewhat depressed for a year, and more or less low-spirited. She had been subject to sick-headaches, less lately than when younger; these continued one or two days with nausea and vomiting. She has had pain in her back and abnormal sensations in her legs. Hands and feet were habitually cold. She had a "thumping and beating" in her head, tinnitus aurium; did not hear voices. She had attacks during which she cried and lay awake nights crying. There were no objective symptoms except a great degree of pallor, lips and tongue as well as skin showing anaemia.

The blood was examined, and there was found a diminution of the red corpuscles, 4,190,000; a very large number were misshaped, being elongated, budded and without concavity.

Valerianate of zinc, iron, and quinine was given, also arsenic; she had massage, and attention was paid to diet and the digestive organs, moderate exercise and as much out-door life as possible.

After five months the patient had gained in flesh, color and spirits. The blood was again examined and showed 4,790,000 red and 10,000 white corpuscles; the deformed corpuscles were very rare, only a few being seen.

The patient was much disturbed by the prospect of leaving, uncertain as to her future, feeling that she ought to take up the duties of life again and yet conscious that she was not able so to do. A visit from a relative, who talked with her on these subjects disturbed her, and she left in a much less cheerful disposition, tearful and despondent.

CASE II. Mrs. N. S. R., was forty-four years old when received. She had been ailing many years, had never been strong. She had no living children; one child was born at seven months; had one miscarriage twelve months before entrance. Her physician told her the cause was the low state of her blood. She did not get up well after the miscarriage; the catamenia appeared six weeks after with much more

pain than on previous occasions. Five years ago her left leg became weak, and there was pain in that limb if she hit her toes while walking. Two years ago the right leg began to trouble her in the same way. She formerly had sick-headaches, but not for some years lately.

Her parents were subject to sick-headaches. Her father's family were consumptive; of eleven only three lived to be thirty-seven years old. Father's parents had headache and neuralgia.

On admission the patient complains of weakness in the legs, with tingling and prickling, not much pain. Sometimes she has backache. She has a fair appetite; does not sleep well. She is low-spirited and despondent. She is not kept awake at night by pain, but by "thinking to no purpose."

The pupils and eyes acted naturally; the tongue was protracted straight, was fissured and fleshy. Sensation was natural and equal in the limbs; motion was not impaired. The patellar tendon reflex was normal; there was no ankle clonus, there was no tremor of the hands; there was a slight degree of tenderness in each groin, rather more on the right, also slight tenderness on each side over the sciatic nerves, the crests of the ilia and the sacro-iliac synchondrosis. There was no spinal tenderness. Pulse was 76, a faint murmur at the apex with the first sound. The patient was pale, anaemic in appearance, seemed to have little or no spirit nor ambition.

Subsequently the blood-corpuscles were examined. There were found to be 4,625,000 red corpuscles; 15,000 white corpuscles. Some of the red were misshapen, being budded, having an elongated shape without concavity. The number of these deformed corpuscles were much fewer than in the previous case.

Under tonics, generous feeding, rest, she gained in flesh, slept better and improved in many ways; at times she was much less despondent, but the gain in cheerfulness was not permanent.

CASE III. Miss F., age forty-two, was never strong; her family history is not good. Her father died insane, her mother is queer, for years she has not seen any one but cousins, and is weak mentally; one brother has an unbalanced mind and is "queer." The patient began to run down when about thirty-three, taking care of her mother. She complained of pain in her legs, abdomen, back and head, sometimes all over. Frequently purpuric spots appear on different parts of the body, especially the legs, during attacks of pain, also on the arms and shoulders.

Mentally the patient is peculiar. She craves attention, is rather inclined to be jealous if others seem to have more attention than herself. At home she taxed the household to wait on her. If she is not humored she lies abed and complains of pain, of weakness. It was a constant contest to get her up and to keep her about after it was evident that she needed to exert herself. She was at times moody, sulky, and had crying spells. She gained much in cheerfulness and in strength, the purpuric spots appeared less frequently, she was evidently much better until it was time for her to go home when she cried much, was less cheerful, had a diarrhoea and sore throat.

The first count of blood was made about a month after entrance, 4,920,000 red, the white at, or just below, the normal. The second count was made about four months later, 4,128,000 red, 20,009 white.

CASE IV. Miss B., age twenty-five, was never

strong, always nervous; probably overstudied in the high school; was obliged to give up studying. She had insomnia, a disagreeable feeling of heaviness in the back of her neck. She became despondent and lost her interest in things about her. She had no headache, but a sense of weight on the top of her head, she felt like screaming.

She was said to be naturally of a quiet, rather taciturn disposition: while at the asylum she preferred to lie out doors, to be by herself, did not voluntarily take part in conversation, but answered when spoken to; her memory was not good, she was negligent in regard to dress. She ate well; slept poorly, though probably more than she thought she did.

Her blood was not examined till she had been there some weeks. There were 3,880,000 red, 20,000 white corpuscles. A few of the red were crenated, a very few were irregular in shape; there were very many small globules or spheroids.

She improved somewhat and subsequently a trip by water to a warmer climate seemed to be of benefit.

CASE V. Mrs. A., age thirty-five, has been ailing for four or five years, had been running down in health for a year when her five children had whooping-cough. For three years or more she has been having nervous feelings, trouble in her head, tinnitus, backache in the lower lumbar region. At times she says she seems to take no pleasure in life, everything seems a burden to her. She is troubled much with low spirits. She has slept poorly. She showed very little of this depression and after three weeks, on account of a child's illness, she left much improved in spirits.

After eighteen months she returned very tired and with many of the old symptoms. In the interval she was much of the time better than previous to her first entrance. Red corpuscles 4,380,000, white corpuscles 10,000.

In two other cases of dyspepsia with much nervous disturbance, but with less depression of spirits than in those just reported, and no other special mental disturbance, a count of the blood gave, in one case, 5,260,000 red and the white below normal, and both red and white rather small in size. The other case gave 5,080,000 red, 30,000 white, a very few of the red showed budded processes. In some cases of simple nervous exhaustion or of headache I have found no change in the condition of the blood as shown by the numbers and shape of the corpuscles.

DR. OSCAR LIEBREICH'S IMPROVED METHOD AND INSTRUMENTS FOR THE EXAMINATION OF THE SKIN, ESPECIALLY IN LUPUS.

BY ARTHUR F. CHADBOURNE, M.D.

A NEW method for detecting and accurately determining the distribution of the so-called "latent lupus," that is, where the process is covered and hidden by an apparently normal epidermis, — was described by Dr. Liebreich in the *Therapeutische Monatsschrift*, for March, 1891. Continued use has proved its accuracy and value, and Dr. Liebreich has most kindly allowed me to describe the method, as now used by him, and to add to it an account of his improved phaneroscope, of which no description has yet been published.

In studying the effects of sodium cantharidinate on lupus of the skin it was often found necessary to wait

several weeks before the superficial growth surely showed the results of treatment, for all changes whether good or bad, begin in the hidden peripheral zone. Even after recovery seems complete, isolated latent nodules may persist here and there, and many cases of "cure" have been reported by different observers, in which the subsequent history showed that the so-called "cure" was undoubtedly only a change to a latent condition, that could not be detected by the ordinary methods of examination. Fortunately the translucency of the skin makes it possible to see abnormal changes in these deeper layers when they are properly illuminated. In almost all parts of the body direct lighting from the side opposite the observer is impossible; but even when this can be done, the thickness of the tissues between the abnormal process and the light, deflects the light rays to such a degree that they cross each other in the superficial layers of the skin, blurring and obscuring everything beneath, and preventing the sharp contrast which is absolutely necessary for the easy recognition of the latent growth. To be of practical value, therefore, the light must be reflected from just beneath the level to be examined, and must pass through and illuminate it before reaching the eye of the observer.

For this purpose Dr. Liebreich has invented the phaneroscope (to be described farther on) but his method can be illustrated, and fairly good results obtained with an ordinary reading lens of about two inches focus and from two to three inches diameter. If the lens is held so that the rays of light from a lamp are brought to a focus a little beneath the surface of the skin, there will be a central, brilliant point of light, and around it a somewhat opaque pink "halo," the latter caused by the rays reflected from the point of focus, which, in returning, diverge and illuminate a much wider circle of overlying skin. If the normal skin, in the neighborhood of a patch of lupus, is first examined, and the lens then moved along parallel with the surface until it is over the typical lupus growth; there is first a widening of the "halo" on the side nearest the lupus, and at a point where the skin seems perfectly healthy; as the more infiltrated tissue is reached this "halo" steadily grows broader, and when the lens is directly over the typical portion of the growth, has become a much lighter pink, glowing circle, two or three times wider than in the normal skin, and much more brilliantly lighted. By approaching the centre along lines radiating from it, the distribution of the disease can be accurately mapped out, and the area will be considerably larger than that found by simple inspection and touch, owing to the addition of the hidden peripheral zone of latent lupus. In this way small detached "islands" of the latent growth are often found, which will probably develop later into typical patches of the disease. A steady and gradual diminution in the width of the "halo," and a darkening of its pink tint show a decrease in the activity of the process and vice versa.

At first Dr. Liebreich used the lens and lamp, but the examination is much more accurate and more easily made with his improved phaneroscope (Fig. 1). In this instrument a small incandescent electric lamp (D) is attached at right angles to a handle (B), through which run wires (C C'), connecting the lamp with a battery. On the upper side of the handle is a switch (A), by which the current can be turned off or on. The incandescent burner is covered by a tube (G),

which holds an ordinary condensing system of two plano-convex lenses (I J) of forty millimetres focus. A second tube (K), ending in a conical tip, with an opening two millimetres wide at its apex, fits over, and can be moved up or down on the lens tube, thus making the focus of the cone of light-rays project the desired distance beyond the tube. By making the focal point project about one and a half or two millimetres beyond the tube, any change in the normal translucency must cause a corresponding variation in the tint of the part of the skin, which is illuminated by the light reflected from beneath it, and as all unnecessary light is cut off by the tubes (G and K), this variation will be much more easily seen than with the combination of direct and reflected light from an ordinary lens. A very important point is that *only the minimum of light necessary for clear definition* should be used.

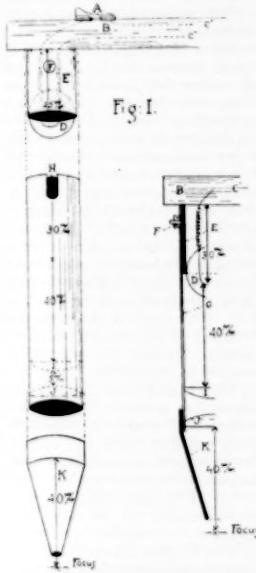

Fig. I.

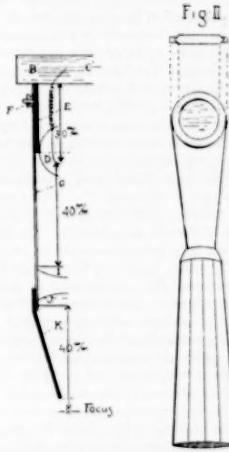

Fig. II.

tory results; and the improvement, though slow,¹ is a steadily progressive one. The "reaction" is never more than slight, and the injections are almost painless. In only a few instances has there been albuminuria, and this has always disappeared within a few hours, so that the treatment could be continued. When pain, severe subjective symptoms or signs of renal irritation follow the use of sodium cantharidinate, the fault must therefore be in the dose or solution used. Dr. Liebreich usually gives subcutaneously 0.0002*i.l.*, and this is repeated from two to three times each week. In all his cases "the process has been arrested and no nodules have developed, which had not been found in the latent condition before the treatment was begun." During the three months that I have spent in his laboratory, Dr. Liebreich has frequently shown me the patients under treatment. Owing to other work I have not been able to follow them carefully, but in every case the process is decidedly less extensive than when I first saw it, and I can recall no case in which there has been even a temporary relapse. From his experiments on animals he believes "that sodium cantharidinate alone will not be sufficient to completely cure a case of tuberculosis," but he is "now combining the 'serum therapy' with other drugs, so that not serum alone shall be brought in contact with the germs, but a serum which shall carry with it a substance capable of destroying the bacteria. This view is strengthened by Henning's pamphlet on Serum-Therapy,² which has just been published."

ORIGIN OF THE RED BLOOD-CORPUSCLES.³

BY CHARLES LOUIS MIX, A.M.
(Concluded from No. 11, page 258.)

III. ERYTHROBLAST THEORY.

In November, 1868, Neumann⁴ and Bizzozero⁵ working independently, discovered almost simultaneously in the marrow of bones certain nucleated haemoglobin-bearing cells which were of the size of white blood-corpuscles, with relatively large nuclei, and which possessed a protoplasm not a hair's breadth different, as Rindfuss⁶ expresses it, from the protoplasm of a red blood-corpuscle in either color, consistency or refrangibility; and both writers declared them to be transitions between colorless cells and red corpuscles. Since that time the primary colorless cells from which the haemoglobin-bearing cells originate, have been named "erythroblasts," by Löwit,⁷ and the term, being a useful one, has persisted. For convenience, I shall extend Löwit's use of the word to include the haemoglobin-bearing cells. Using the term

⁶ Löwit: "Der Kurze halber werde ich diese Zellen, die zur Neubildung rother Blutkörperchen in uniglobular Beziehung stehen, als Erythroblasten bezeichnen." Page 56 of the above article.

⁷ Improvement is not expected much before the 100th injection.

² Henning: "Wesen und Werth der Liebreichsche Serum-therapie," Leipzig, 1892.

To distinguish hyperæmia from blood which has escaped from the vessels into the surrounding tissues, Dr. Liebreich uses, what he calls, a "glass pressor": a small plate of flat glass held in a light handle (Fig. 2). By looking through the glass one can see the changes that take place while the pressure is being made, as it is not necessary to remove the "pressor" to see the skin beneath it.

The value of an examination made in the way just described, is not confined to lupus, but is useful in the diagnosis of all conditions involving hyperæmia, hypertrophy, pigmentation or haemorrhage of the skin, and has been an especial help in the recognition of crystallous tissue.

The cases of lupus treated by Dr. Liebreich with cantharidinate of sodium have all given most satisfa-

in its extended sense, erythroblasts have also been found in the spleen and lymphatic system in cases after very severe bleeding.

In order that an erythroblast, after acquiring haemoglobin, may develop into an ordinary red corpuscle, two things are necessary: (1) it must lose its nucleus, and (2) it must become a biconcave disc. The great question is — "How?"

There have been three theories for the loss of the nucleus, that of Malassez, which for convenience is now given second, being chronologically last.

Neumann²³ supposed that erythroblasts lost their nuclei by absorption preceded by fragmentation. He gave descriptions of the first stages of the process showing the nucleus notched and indented, and also of the final stages, showing a last fragment still remaining in the cell. He took for granted an intermediate series connecting the extremes, but was unable to show any preparations. This absorption theory was an old one advanced by Kölliker²⁴ to explain how certain embryonic nucleated cells of the blood of the liver became non-nucleated red corpuscles; but he was forced to confess that he could not follow out the process of an entire absorption. It is for lack of histological proofs, therefore, that the Neumann-Kölliker theory failed.

The absorption theory has also been ingeniously disproved in another way by Malassez. He shows that in some cases where the erythroblasts are relatively very much larger than the red corpuscles, that one erythroblast would make a corpuscle from four to twenty times too large, by the simple absorption of its nucleus. In an erythroblast from a kid, the shell of protoplasm surrounding the nucleus varies in thickness from .375 μ . to .750 μ . at any point; and its volume, obtained by finding the total volume of the erythroblast and then subtracting the volume of the nucleus, varies from 25.2 cu. μ . to 127.3 cu. μ . But the volume of a corpuscle from a kid contains only 6.38 cu. μ . Hence one erythroblast would give rise to a corpuscle from four to twenty times too large.

(2) Influenced largely by this calculation, Malassez²⁵ advanced a new theory, that of budding. He supposed the protoplasm of the erythroblast to give off buds just as do yeast-cells, the buds being constricted off when they have reached the volume of the corpuscle which they are destined to form. They are roughly spherical at first, but become, after separation from the erythroblast, biconcave, by being flattened in the circulating blood by contact with other globules, something as the shingle on a well-washed beach,²⁶ and also by a slight loss of water. Malassez's chief argument in favor of his theory is that the buds always correspond closely in volume to the red corpuscles, and that their size is never influenced by that of the erythroblast from which they develop. For example, in the kid the erythroblasts are much larger than the corpuscles; hence the buds are relatively small. In the rabbit, however, the erythroblasts are only a little larger than the corpuscles, hence the buds are as large as the

Il se passe peut-être pour les globules circulant quelque chose d'analogique à ce qui se passe pour les galées de la mer, qui, attirées par le poulard et agitant sansesse pour faire leur exercice, réussissent par s'user sur deux de leurs faces opposées, par devenir plates."

erythroblasts themselves. In all cases the bud is a sphere of such a volume that when compressed its diameter will equal that of the biconcave discs.

(3) Rindfleisch,²⁷ shortly before Malassez's paper appeared, advanced his theory of the extrusion of the nucleus; and in a recent paper Dr. Howell²⁸ supports him. Rindfleisch gave figures showing that the nucleus is forced out of the cell, and stated that it is extruded, surrounded by a protoplasmic film, leaving a bell-shaped shell of protoplasm behind which develops into a red corpuscle. Dr. Howell has been able to show numerous cases in which the nucleus is extruded, and claims that in no less than three cases he saw in part the actual extrusion take place in living cells. He, however, differs from Rindfleisch in one important point: he says the nucleus is extruded absolutely devoid of protoplasm as far as he could discover, using his highest magnifying powers.

While experimenting upon cats, Dr. Howell came upon an appearance which he thinks corroborates his theory. He observed in the periphery of corpuscles newly-formed after severe bleeding, a fragment of deeply-staining substance which he explains as a fragment of the extruded nucleus left behind, due to the rapid formation of corpuscles brought about by extensive losses during bleeding. Dr. H. P. Bowditch suggested that he use this fact as a means of finding the average term of life of a corpuscle, but unfortunately nothing has as yet come from the suggestion.

In regard to these three theories it may be said in conclusion that the last two are essentially identical; for what is the difference whether a bud of protoplasm be constricted from a nucleus, leaving a film of protoplasm about it according to Malassez, or whether according to Rindfleisch and Howell, a nucleus with its film be constricted from a mass of protoplasm, or, as they say, "extruded"? The result is the same and the process is doubtless the same, though looked at from different standpoints. Though Dr. Howell did not see any protoplasm about the nucleus, it is doubtless present, and has been seen by enough observers to warrant the conclusion that it exists. As far as I know there is no well-authenticated, undisputed case of a free nucleus, even the parablast nuclei or merocytes having been shown to possess protoplasm. It is, therefore, probable that the extruded nuclei are invested by a thin protoplasmic film. This combined theory for the loss of the nucleus seems to be the true one.²⁹

The next question is, how do these masses of hemoglobin-bearing protoplasm become biconcave discs? At present there are two explanations offered. Rindfleisch says that they are flattened by being rolled about in the blood-stream. Malassez agrees with him and says that the process is further aided by a shrinkage caused by a slight loss of water. Dr. Howell's explanation is exceedingly sensible and equally simple. The biconcavity and flattening are produced by the loss of the nucleus from the interior.

How do the biconcave discs when formed get into circulation? Rindfleisch has a simple answer to this question, obtained by careful injection in the marrow of the ribs of a guinea-pig. In 1869, Hoyer³⁰ showed

²⁷ Rindfleisch: *Archiv. f. mikr. Anat.*, Bd. xvii, pp. 1-21.

²⁸ W. H. Howell: *Journal of Morphology.*, vol. iv, pp. 55-116.

²⁹ Malassez, as quoted by Gibson, confesses that he has seen the buds described by Malassez, but believes that they are very rarely caused chiefly by reagents, especially by cosmic acids. Dr. Howell also admits that he has seen the buds, but he regards them as daughter-cells which, by extrusion, have lost their nuclei before they are completely separated from the mother-cells.

³⁰ Hoyer: *Contribut. i. die med. Wissen.*, Bd. x, 1869, No. 17.

that the marrow is rich in arterial and venous capillaries, the former having very thin walls, the latter possessing none at all, being hardly more than lacunae between marrow cells. Ten years later, in a paper already quoted, Rindfleisch was enabled to prove the truth of Hoyer's statements by his injections. Hence it is an easy matter for new corpuscles to get into circulation. Very striking is the fact that, in the nutrient artery, the media is reduced to a single layer, the muscularis, the elastic layer being absent altogether; and that furthermore the adventitia is very thin. This may be explained by the fact that the artery enters the long bone in a direction very oblique to the long axis, the bony walls therefore serving as arterial walls. If, therefore, the latter be so much reduced, it is not surprising that the venous capillaries are without walls; and furthermore, being placed inside the bone, they hardly need them.

Neumann contradicts Hoyer and says that with careful injections a thin-walled system of venous capillaries can be demonstrated,⁴⁵ although he acknowledges that in some pathological cases it seems to be absent.⁴⁶ He says that the erythroblast, since they are capable of amoeboid motion before becoming infiltrated with hemoglobin, make their way bodily through the walls of the venous capillaries into the enlarged lumen of these vessels where they develop into red corpuscles. In support of Neumann's view, Denys⁴⁷ has shown conclusively, that, in the bones of birds, the venous capillaries possess walls and that the erythroblasts lie in cords within the enlarged lumen, the blood-plasma percolating between them. From the condition in Aves it is very natural to conclude *a priori* that the condition in Mammalia is much the same; hence Neumann's explanation of how the blood-corpuscles when formed pass into circulation is more satisfactory than Rindfleisch's.

The last question to be answered is, What is the fate of the extruded nucleus? No one, so far as I have learned, has faced this question except Dr. Howell,⁴⁸ Rindfleisch,⁴⁹ who believed in the absorption of the nucleus, did not need to answer it. Malassez⁵⁰ implies that the nucleus of the erythroblast, when stripped of most of its protoplasm by the developing bud, simply acquires more until it is ready to produce another bud. Neumann,⁵¹ Osler,⁵² and others describe free nuclei⁵³ in the marrow of the adult, and in the liver and spleen during fetal life. Dr. Howell says that these are the extruded nuclei in question, and that they are ultimately dissolved in the blood-plasma. He thinks that they may form the fibrinogen of the blood, for after bleeding, when of course the numbers of free nuclei are greatly increased, due to the rapid formation of new corpuscles, it has been found that the fibrinogen of the blood is increased sometimes one hundred per cent. This is very significant when placed beside an observation of Malassez, although so far as I know no one has put the two facts together. Malassez⁵⁴ noticed that in teasing the erythroblasts he

often broke into the nuclei, and in all cases they proved to be of a semi-fluid nature containing a stringy, fibrous substance, of which he gives figures. This might lead one to think that he had actually caused the formation of fibrin in the nuclei of these cells by contact with the needles during teasing, and so it becomes a striking confirmation of Howell's suggestion.

What is the origin of the erythroblasts? Here we once more enter upon disputed territory, the leading theories being divisible into two classes: those not concerned with the marrow, and those concerned with it. Of the first group the following are the most important:

(1) Erythroblasts arise from each other by ordinary indirect cell-division. This fact, first pointed out by Bizzozero many years ago, has received abundant confirmation since then by almost every writer upon the subject; still, though undoubtedly true, it cannot be received as a satisfactory explanation of the ultimate origin of erythroblasts.

(2) Bizzozero has advanced another theory which has received many supporters; namely, that the erythroblasts have arisen from nucleated embryonic corpuscles which during fetal life found their way into the marrow where they have since remained. Bizzozero therefore regards the erythroblast as a cell *suo generis*, entirely distinct from marrow-cells.

(3) Neumann in his first paper, as has already been said, advanced the theory that erythroblasts were merely transformed white corpuscles, but lack of histological proofs of such a transformation led to the overthrow of the theory. Neumann's observations were undoubtedly much more correct than his explanations. The series of transitions which he claims to have seen between a leucocyte and a red nucleated cell ready to become a corpuscle by loss of its nucleus, undoubtedly existed; but the cell which began the series was very likely a marrow-cell instead of a leucocyte. Curiously enough Bizzozero in his first paper advanced the theory that leucocytes develop into red corpuscles, passing through the erythroblastic stage; but both he and Neumann revoked their first opinion in consequence of the arguments raised against it.

(4) Erythroblasts have been thought by Pouchet,⁵⁵ who has been the author of many theories, to arise by an indirect process from what he calls "hyaline leucocytes," supposed to be derived from pre-existing larger cells. Just as we have fatty or pigmentary degeneration of cells, so we have in "hyaline leucocytes" a haemoglobin degeneration. As Malassez points out, there is anything but a degeneration in the erythroblasts, they being on the contrary very active in cell-division. Besides, a true leucocyte has never been seen to become impregnated with haemoglobin, much less to undergo a haemoglobin degeneration. Pouchet seems to have had scarcely any histological evidence for his hypothesis.

(5) Erythroblasts have been known to occur in the adult spleen, but only after severe hemorrhages, originating from other indifferent colorless cells. This was first shown by Bizzozero, afterwards experimentally proved by Gibson, and substantiated by Howell

⁵² Osler: Cyclopedia of Medicine, New York, 1878. (Philadelphia.)
⁵³ Though these nuclei are described as free, they probably possess some protoplasm, however small in amount it may be.

⁵⁴ L. Malassez: Arch. de Physiol., vol. ix, 1882, p. 24. When one teases a preparation of marrow, "on y trouve, au milieu d'éléments

plus ou moins déformés et déchirés, de très fins filaments. . . . Quand la dissociation a été faite systématiquement, suivant un seul sens, d'avant en arrière, par exemple, presque tous les filaments ont cette même direction. . . . Il suffit suffisamment de faire tout ce processus si on arrive à faire suffisamment liquide et filante que l'entrainement qu'il y a pour les aiguilles dissociatives, seraient étrier en fils et par places rassembler en larmes ou en boules."

⁵⁵ Pouchet: De la Degénérescence Hémoglobinaire de la Moelle osseuse. Soc. de Biol., March 15, 1879; also Gaz. Médic., 1879, p. 184.

Gibson⁴⁷ excised the spleens of three dogs and in two cases found an actual decrease in the number of red corpuscles. Bizzozero says that this is to be regarded as the return of the spleen to an embryonic function, occurring only when the demand upon the marrow for corpuscles exceeds the possible supply, as after severe bleeding. Very interesting is the additional fact that when part of the spleen is excised, the newly growing portion develops erythroblasts as it did during its formation in the embryo. Löwit⁴⁸ thinks that the spleen and lymphatic glands are constantly preparing colorless erythroblasts, destined to acquire hemoglobin, and, by the loss of the nucleus, to develop into red corpuscles. No one seems disposed to agree with him in regarding the spleen as normally forming erythroblasts in the adult.

(6) Erythroblasts occur in the lymphatic glands, though where they come from is not known. We are indebted for the knowledge of this fact to Gibson, who ligatured the thoracic duct of a dog thirty-seven days before the animal was killed, it having gained five decagrams in the meantime. Post-mortem examination showed erythroblasts present in the left axillary glands and especially in the abdominal ganglia, there being only a few in the right axilla. A calculation of the numbers of red corpuscles before death showed a loss of thirteen per cent. Furthermore in the marrow-cavity in the shafts of both humerus and femur there had been an extension of the marrow, thus indicating that, since the lymphatic system had been unable to furnish its quota to the sum total of the blood, due to the ligature about the thoracic duct, the hematopoietic function ordinarily performed by the lymphatic ganglia had been imposed upon the marrow. Löwit also regards the lymphatic system as a normal source of erythroblasts.

It is in the marrow, however, in which most to-day agree that erythroblasts normally originate. There are to be found in the marrow in addition to the three elements of the blood, red and white corpuscles and blood-plates, the following sorts of cells:

(1) Certain colorless cells, which possess granular nuclei with no definite nucleoli, and which are exactly like red nucleated corpuscles before they have lost their nuclei in everything except the possession of hemoglobin. These cells are the erythroblasts of Löwit.

(2) Haemoglobin-bearing cells, which are just on the point of losing their nuclei by extrusion and which develop immediately into red biconcave discs.

(3) Wandering-cells or leucocytes, numbering nearly one-half the total number of cells found in the young marrow.

(4) Giant-cells, which are of two sorts, one possessing an elongated and nodulated nucleus, described very well by Bizzozero as the cells with the "budding nuclei"; the other possessing a number of nuclei, described by Robin under the name of "myeloplasa," and participating largely in the destruction of bone during the bone-making process. It is not probable that the first sort ever develops into the second.

(5) Free nuclei, described by Neumann as occurring in the liver, and by Oeler and Obrastzow as occurring

also in the marrow, regarded by Dr. Howell as the extruded nuclei of erythroblasts.

(6) Ordinary marrow-cells, possessing a slightly granular protoplasm containing an oval or sometimes rounded nucleus, and a nucleolus. Another sort has been described as being coarsely granular, staining deeply with eosin, and possessing a nucleus with one or more nucleoli.

(7) Fat-cells, found in older marrow. From all of these cells, except the fat-cells, it has been supposed that erythroblast may develop, but the weight of evidence seems to be in favor of ordinary marrow-cells as the true source.

Many theories have already been given attempting to show that erythroblasts arise from leucocytes. One of the first was Küller's, and it was followed in 1868 by Neumann's and Bizzozero's. None of these writers make use of the term "erythroblasts," yet they have described them as occurring in their series of transitions. Pouchet's theory that certain hyaline leucocytes found in the marrow developed into red corpuscles, after passing through the erythroblastic stage, has been mentioned.

Foa and Salvioli⁴⁹ state that the giant-cells with the "budding nuclei" of Bizzozero give rise to colorless erythroblasts by a process of constriction, the erythroblasts then becoming colored with haemoglobin and forming corpuscles. They call these giant-cells "hematoblasts." Rindfleisch⁵⁰ believes that the giant-cells by a series of transitional forms pass to the red corpuscles through an erythroblastic stage, although he does not, of course, call it by that name.

Oeler⁵¹ and Obrastzow⁵² believe that the naked nuclei of the marrow do not dissolve in the blood plasma as Dr. Howell suggests, and that they are not extruded nuclei of erythroblasts, but that on the contrary they develop into them by first becoming surrounded with protoplasm, which is then infiltrated with hemoglobin, thus giving rise to red blood-corpuscles by the subsequent loss of the nucleus. The theory is not well supported.

Malassez,⁵³ Howell⁵⁴ and Gibson⁵⁵ all unite in believing that erythroblasts develop from ordinary marrow-cells. Until 1890 not all the stages had been satisfactorily shown, but during that year Dr. Howell gave additional evidence of the truth of the theory. Malassez does not give a clear account of the origin of the erythroblasts which he names "protohaemoblasts,"⁵⁶ contenting himself by saying simply that the latter arise directly from undifferentiated marrow-cells. According to Dr. Howell the marrow-cell first develops into a cell, which is the exact counterpart of a nucleated red corpuscle, but which possesses no hemoglobin, thus corresponding to Löwit's erythroblast. This then acquires haemoglobin, and after passing through an unknown number of generations, during which time there is a gradual change in the nucleus preparing it for the fate awaiting it, the cell becomes fully matured, and loses its nucleus by extrusion, thus developing into a true corpuscle. Of all the theories

⁵⁶ L. Malassez: Op. cit., p. 35.

which have been advanced for the origin of the erythroblast, the last is undoubtedly supported by the best histological evidence.

As the question of the origin of the red corpuscles of the adult now stands, there are only two theories which can claim to be at all established, Schäfer's Vaso-formative theory and the Erythroblast theory. Unfortunately the former is active only a short time after birth, so that it cannot be given as a sufficient explanation. The erythroblast theory rests on excellent evidence, is a sufficient explanation, but unfortunately exists in so many variations that many are disposed to doubt its truthfulness altogether. Whoever will undertake, however, to run over all the many theories from Neumann's time to the present day, can hardly fail to see that, although stated in so many forms, they yet reduce to one, which in brief seems to be as follows: An indifferent marrow-cell with its granular protoplasm, nucleus and one or more nucleoli, by a series of cell-divisions, develops into a nucleated colorless cell, which by an amoeboid motion makes its way into the lumen of a venous capillary. Here it acquires hemoglobin, and passes through a series of changes fitting it for the loss of its nucleus which takes place by extrusion. After the loss of the nucleus, the plastid, no longer a true cell, collapses, and is transformed into a biconcave disc or red blood-corpuscle, which passes out of the marrow-cavity into general circulation.

Clinical Department.

A CASE OF IMPERFORATE RECTUM.

BY W. M. CONANT, M.D.

WHEN making the visit Sunday, May 31, 1891, at the Massachusetts General Hospital, for Dr. Homans, I found a male babe, three days old, that had passed no feces since birth. The child had vomited frequently. The urine was passed freely, clear, and not tinged with meconium. Temperature at time of entrance 100°, pulse 100.

Examination showed the child to be much jaundiced. General condition fair, with pulse of good strength. Abdomen much distended, so that the veins could easily be seen. No anus present, not even a dimple to mark the accustomed spot. A doubtful impulse was felt in region of anus on pressure upon the abdomen.

The child was seen in consultation by Drs. Beach and Mixter, and it was decided best to operate.

Operation, under ether. Drs. Beach, Mixer and A. Coolidge, Jr., present. An incision was made from the middle of the perineum to tip of coccyx, and was carried to the depth of one and a half inches. Even then there was no impulse to be felt either by Dr. Beach or myself. A small trocar was plunged into the region of the rectum, but nothing was obtained. It was decided that it was not wise to deepen the incision, and on consultation it was thought best to do a laparotomy.

An incision two and a half inches long was made in the left linea semilunaris. Some ascitic fluid was found on opening the abdominal cavity. On inserting the finger the distended bowel was detected, extending toward the perineal incision. It seemed to be about a quarter of an inch from the perineal incision, and sep-

arated from it by a diaphragmatic membrane which shut off the abdominal from the pelvic cavity. Then it occurred to me that it might be possible to pass a trocar through the perineal wound into the gut. This I was able to do by using one finger in the abdominal cavity as a guide. The point of the trocar held in the other hand was directed as far back as possible and then entered the bowel from behind without opening the peritoneal cavity. A good-sized trocar was passed into the gut, and five ounces of meconium passed through the canula. The abdominal wound was closed with silk sutures. The canula was left in perineal wound, being fastened in with adhesive plaster. The child stood the operation well, and slept in the afternoon. He took and retained milk and water when awake. Feces passed readily through the canula, and the child was very comfortable in the evening.

Through the kindness of Drs. Homans and Cabot, I was permitted to have the subsequent care of the case.

June 4th, three days after the operation, the canula was removed and a rubber tube fastened into the wound.

June 15th, two weeks after the operation, the child had gained a pound in weight, now weighs seven pounds. Abdominal wound healed.

June 30th. Several times in last two weeks the anus has been dilated, and to day a fresh tube was inserted. Weighs seven pounds. The abdomen bulges a little at cicatrix, due to the thinning of the entire abdominal wall.

July 15th, six weeks after the operation, child still weighs seven pounds. Food does not agree with him at this time.

July 31st. Anus stretched and a mass of faecal impaction dug out. Has lost one pound in weight. Several different foods were tried, and it was found that half barley-water and milk agreed best with the child.

The child remained in this condition, sometimes losing, sometimes gaining, in weight, until the last of August, and then, during a few days of extreme heat, he had an attack of enterocolitis, and died.

The entire subject cannot be covered in a paper of this character, but a consideration of the more important points may be of value.

In the embryo a cloaca exists until after the fifth week, and the genital eminence makes its appearance in the course of the sixth week in front of, and within, the cloaca. In the seventh week this is divided into two parts, just how this takes place is not known. The process is connected with the formation of the urogenital cord as an independent structure, and results in the division of the cloaca into a dorsal or anal, and a ventral part. In the tenth week a transverse integumental band completes the division. Of the two openings the dorsal one or anus is of small size and is surrounded by a small, circular, integumental ridge.

It follows, therefore, that there may be several different forms of imperforate rectum or anus, namely:

- (1) The anus may be partially closed.
- (2) The anus may be completely closed.
- (3) The anus is closed, but there is an opening into bladder, urethra or vagina.
- (4) Anus and rectum imperforate.
- (5) Anus in natural position, but rectum wanting for a short or long distance.

The anatomy of the rectum of the infant has been but little studied judging from the small amount of literature on the subject. I have measured a few babes

at term at the Harvard Medical School, and have found the antero-posterior and lateral diameter, from the tip of the coccyx to symphysis on each, about an inch. The distance from the anus to the brim of the true pelvis is a little less than two inches. One interesting thing that I noticed was that about two inches up the rectal wall there was a sharp falciform edge felt as if the rectum was flexed at that point. This I have also felt on several babes a few months old. How much weight, if any, ought to be attached to this point I am unable to state.

The prognosis of these cases, except the simplest forms, is very unfavorable.

Cripps has tabulated one hundred cases of Littré's operation with five recoveries.

Holmes claims not to have met with an account of any permanently successful cases since the publication of Rochard's paper.

Geraldes, after thirty trials, had one successful case, and that died at two and a half months.

Guersant opened the colon in the groin eleven times and once in the loin, without saving a single patient.

Inflammation, visceral complications, dilatation of the bowel above with retained ingesta, insufficient assimilation and pain render a favorable result very improbable.

Treatment. — All operators agree that the indications are to establish an opening as near the natural position of the anus as possible.

The first two forms, where the anus is partially or completely closed, are easily treated by breaking down the membrane and keeping the gut patent by occasionally inserting the finger.

In the third form, where there is a fistula, several things have to be considered. Where there is a recto-vaginal fistula, the size of the child and the urgency of the case have to be considered. Most operators advise waiting until the child is several years old. When the fistula empties into the urethra or bladder, the amount of rectum wanting and the height of the communication are important points. Where there is bulging at the anus the communication is probably recto-urethral, and an attempt may be made to find the bowel. If the bowel cannot be found, Littré's operation is advised by most operators.

In the fourth and fifth forms, where, with anus perforate or imperforate, the rectum is deficient, we have the most difficult problems to solve. In these cases Jacobson mentions four points that should be remembered: (1) Rectum may end at brim of pelvis. (2) If the rectum ends lower down, it may be floating with a long meso-rectum. (3) Though the rectum may end within reach, the peritoneum may, and not infrequently does, extend low down on the bowel. (4) Even if the rectum is successfully opened high up without opening the peritoneum, fatal cellulitis may be set up by the escaping feces, or by the attempts to keep the bowels patent.

Nearly all operators advise an exploratory incision in the site of the anus, and some advise carrying this to the depth of two inches; this is the extreme limit. The majority advise an inch or an inch and a half. At this depth a small trocar or aspirating needle is advised to be inserted well toward the back: failing in this, they advise Verneuil's operation, namely, excising the coccyx, inguinal colotomy, lumbar colotomy, Littré's operation.

Verneuil's operation has been performed but seldom,

but in certain cases it seems of promise. Lumbar colotomy is not often done at present as inguinal colotomy or Littré's operation is preferred.

After having found the gut by Littré's operation, it is an interesting question to decide whether an opening should be made through the perineum. The authorities differ, but the consensus of opinion is against doing so, because it is not certainly known where the gut is or whether it is covered with peritoneum. This may be true in the usual methods of operating, but in the case just reported the end of the gut could have been found wherever it was; and the ability to direct the trocar toward the back of the pelvis was very marked. Certainly, this method enables one to know just what one is doing.

This is the first case, as far as I can learn, that has had a laparotomy performed, and then had a connection made between the gut and the perineal wound without opening the intestines from above. Certainly one case does not prove anything, but the unfavorable condition of the child before the operation, and the great relief and slight shock from the operation, has led me to report this method of operating in severe cases of imperforate rectum and anus.

Medical Progress.

RECENT PROGRESS IN DERMATOLOGY.

BY JOHN T. BOWEN, M.D., BOSTON.

(Continued from No. 11, page 265.)

PIGMENTATION OF MUCOUS MEMBRANES IN "VAG-ABOND'S DISEASE."⁴

PIGMENTED spots of the mucous membrane are generally considered a characteristic and even pathognomonic sign of Addison's disease. In a case of generalized pigmentation their absence is almost enough to warrant us in eliminating Addison's disease. While these diagnostic deductions are true in the immense majority of instances, the two cases reported by Thibierge, show that some modification in our statement of them is necessary. The first case was that of a man fifty-nine years old, who had fallen from a respectable position, into habits of confirmed vagabondage. A discoloration of the skin had appeared a year before, and of late there had been great pruritus of the whole body. When examined his clothing was found to be infested with pediculi, and his skin bore the marks of having been exposed to the attacks of these parasites for a long time. The upper part of the back, and the parts which were brought most closely into contact with the clothing, were covered with the characteristic linear excoriations, mingled with ecthymatos pustules. Almost the whole surface of the skin was covered with a marked pigmentation, more pronounced about the waist in front, and in the scapular and sacral regions behind. The scrotum was pigmented, but not to the degree common in Addison's disease. The mucous membrane of the mouth was the seat of numerous brown patches, irregularly distributed and sharply defined. The glans penis also showed some dark brown spots, as well as the mucous surface of the prepuce.

The second case was that of a former coachman,

* *Bulletin et mémoires de la Société des Hôpitaux de Paris, December 18, 1891.*

seventy years of age, who had led a miserable existence for two years, in great poverty. The body was pretty generally pigmented, with the addition of the other characteristic lesions of *pediculi vestimentorum*, excoriations, pustules and furuncular lesions. The face slightly pigmented; the mucous membranes of the mouth, as in the preceding case, covered with pigment spots, and the border of the lower lip with dark brown patches. Pigmentation also upon the glans.

These two cases represent well the pathological condition of the skin, to which the name "vagabond's disease" has been given, where the skin, in subjects who have been living in great misery and without sufficient nourishment, takes on a deep brown tint, resembling that seen in Addison's disease, on account of long-continued irritation from *pediculi vestimentorum*. In vagabond's disease, however, we have been accustomed to regard the mucous membranes as not affected, a marked distinction from Addison's disease. In the two cases cited, however, there was no evidence of the latter disease, and as two similar cases have been reported, one by Greenhow and the other by Besnier, Tibierge concludes that the pathognomonic value of pigmentation of the mucous membranes in Addison's disease may well be doubted.

CHRONIC RINGWORM IN AN INSTITUTION.

Dr. Dubring's experience in the treatment of chronic ringworm in an institution,⁵ illustrates once more the obstinacy of this affection, and offers valuable suggestions for its management. Ringworm had been prevalent in the institution for a number of years, and was steadily spreading in spite of the care of physicians and attendants. Forty-eight subjects, boys whose age varied from eight to twelve years, were found to be affected with ringworm of the scalp, as proved by microscopic examination. The affection was, in most instances, chronic, having existed from six months to three years, the average duration being about a year. All lived in the infirmary and had been isolated from their fellows. No reason could be found for the persistent spread of the disease, as the institution was clean, and the management and attendance most satisfactory. The nutrition of the subjects was, on an average, somewhat below par, although some few were even robust. Thirty-two of the forty-eight cases are described as bad ones with regard to their extent and chronicity. Some had been considered cured and had left the infirmary, only to return sooner or later with a recurrence of the affection. In some cases the whole scalp was more or less affected. The hairs were mostly broken off near the scalp, giving the appearance of dark or light points. The epidermis was very slightly affected, as a rule; no cases were seen where anything suggestive of *alopecia areata* was present.

The treatment, with which the paper especially deals, was conducted systematically and thoroughly.

The hair was cut short about once a week on an average. Epilation was found to be very difficult to enforce, although its advantages are conceded by the writer. In choosing the remedies, the age, complexion and general nutrition of the patient were considered. The boys of dark complexion were able to bear much stronger preparations than those with light hair.

Carbolic acid proved disappointing, although used in a large number of cases in the form of ointment, or as a mixture with olive oil and glycerine, and the

writer, from his experience in these cases, is inclined to allot it a low rank in the list of parasiticides. It could be used in full strength without causing much cutaneous disturbance. Tar was used chiefly in combination with carbolic acid or sulphur, but with no favorable results.

Iodine also, used as a tincture, or in combination with tar, was unsatisfactory in the chronic cases. Its failure to act is attributed to the fact that it is a diuretic and while the epidermis is being thrown off, there is no remedy in contact with the scalp.

The oleate of copper, and the mercurials were thoroughly tested, without giving marked results. Corrosive sublimate was not deemed a safe drug to use, in view of the large extent occupied by the disease in most of the cases.

Crotone oil did good service by its inflammatory action, being prescribed with olive oil one part to three, and in this strength proved safe and effective. After pustulation had been in this way established, mild sulphur or calomel ointments were used to control it. No unfavorable results from the oil were noted, and in general, although extensive and severe local inflammation was produced by many of the remedies tried, no case of eczema developed.

The best results were obtained from sulphur and from chrysarobin, especially from the latter. Sulphur was used as an ointment, in strength varying from one to three drachms to the ounce. It was found also to be very serviceable as a weak ointment after the stronger remedies had been applied. Various combinations of sulphur with soap, with tar ointment, and with carbolic acid were prescribed, but it was considered to be more effective when used alone.

Chrysarobin proved to be the most efficacious parasiticide employed. It was at one time or another employed upon the greater number of patients, and is spoken of with great praise. Twenty-nine cases were treated with this drug, in only seven of which was any irritation of the scalp produced. It was used in strengths varying from fifteen grains to two drachms to the ounce of ointment, the usual strength being one drachm to the ounce. In one instance it caused edema of the whole face, and in one it was applied to the whole scalp without causing excessive inflammation. Pain in the head was complained of in but one instance, while in several, the whole scalp was somewhat inflamed without causing heat or pain. In some instances the forehead and sides of the face became stained without affecting the eyes. The desquamation following the inflammation was of a peculiar nature, consisting of large, thick, papery scales. The writer concludes from his experience with these cases — which were all chronic and had been previously treated with strong remedies — that there does not seem to be much danger from chrysarobin if applied under the physician's own supervision, and if the application is sparingly made, the face avoided, and the strength gradually increased. Its exhibition always requires caution. Its efficacy is attributed to its power of destroying the fungus by penetrating the follicles. It should be used in very small quantity, and rubbed in with a small bit of cloth or a mop.

ENGLISH VIEWS OF LUPUS.⁶

The discussion on lupus, held in the Section of Medicine at the annual meeting of the British Med-

⁵ British Medical Journal, October 10, 1891.

⁶ American Journal of the Medical Sciences, February, 1892.

ical Association in Bournemouth, July, 1891, is interesting chiefly on account of the almost unanimous consensus of opinion in favor of the tuberculous nature of lupus.

The discussion was opened by Dr. Payne, whose conclusions may be quoted at length. "Lupus may be regarded as a very slow and chronic form of the tuberculous process, remaining for the most part local. It differs from other forms of tuberculous disease chiefly in its slowness, its feeble infectivity, and the paucity of tubercle bacilli. Probably for these reasons it remains commonly confined to the organ (skin) in which it originates, and often to one part of it. It is a plausible hypothesis that these differences depend on the production of a weakened virus, or on the bacillus growing in unfavorable circumstances, as compared with the conditions present in internal parts. Now the most striking difference between the skin and the internal viscera is that of temperature. The temperature of most internal organs is probably about 100° F., while a surface thermometer applied to the skin is with difficulty brought up to near 90°, and in exposed parts with free radiation the temperature of the skin is probably on an average not much over 80°. This difference will be greater if the cutaneous circulation is sluggish, and also where there is much subcutaneous fat, one function of which tissue appears to be to allow the skin to have a temperature different from that of internal organs. Furthermore, internal tuberculous lesions always give rise to some fever, which is not the case with tuberculosis of the skin, and this further heightens the contrast, so that the temperature of an external tuberculous lesion may very well be 20° lower than that of a visceral lesion. The temperature and conditions of tuberculous disease of joints would, I should imagine, be about intermediate between the two. It is known that the 'optimum' temperature for the growth of the tubercle bacillus is about 100°, and, though it has been lately shown that it will grow at lower temperatures than has been supposed, the growth, under such circumstances, appears to be slow. It has not been ascertained, so far as I know, whether cultures grown at a low temperature are actually less virulent, nor whether the ptomaines, or other chemical substances they produce, are different, but while the bacillus grows so slowly, it seems certainly probable that there would be a difference in these respects also. I conclude, then, that the skin is a poor soil for the growth of the tubercle bacillus, and that though it may persist there, its condition is not flourishing.

"Looking at the question all round, it would seem, too, as if the bacillus were not easily made to take root in the skin. Inoculated tubercle, as I have said, seems very often to die out, without penetrating further. The bacillary growth of scrofulous glands or subcutaneous nodes, when it reaches the surface, mostly dies off, only exceptionally extending along the skin and producing lupus. Lupus on the surface of the extremities, as Mr. Hutchinson remarks, and as I can affirm, often dies off spontaneously, probably from the low temperature. The face is a more favorable soil, on account of the congestions and disturbances which are caused by the special blood-supply of that region; but anywhere it seems as if the bacillus had a difficulty in establishing itself, and when it does, it passes into a slowly vegetating form of slight virulence. When lupus is inveterate, as I before re-

marked, it seems to have almost lost its infective power, rarely producing new patches, and in such a case we have a bacillus that has been cultivated for many years at a low temperature, and would, therefore, be presumably less virulent."

With regard to the mode of infection, Dr. Payne considers first the probability of a direct inoculation of the skin through a wound or otherwise, and although in most instances this mode cannot be established, he does not doubt that instances of inoculation will be multiplied in the future. The other hypothesis is that of direct inheritance. He considers that the occurrence of absolutely congenital tuberculosis in bovine animals is clearly proved, and that there are one or two cases of the same kind in the human infant. Baumgarten is regarded as having drawn his theory much too far, especially in minimizing or even denying the possibility of infection with tubercle bacilli through the breath or otherwise, and there is a difficulty also in assuming such a long period of latency as is required to explain many cases of tuberculous disease on this theory. Direct inheritance of tubercle, if established, would explain very well the origin of many cases of lupus.

Mr. Calcott Fox, who followed, declared that the identity of what has been known as scrofula of the bones, joints, glands and skin with true tuberculosis must be admitted. True lupus (as distinguished clinically from scrofuloderma) could undoubtedly arise from these scrofulous lesions. His statistics, comprising eighty hospital cases of true lupus, entirely confirmed the facts: first, that scrofulous or tuberculous lesions of the skin, bones, glands and joints frequently complicated lupus cases; and secondly, that a family history of tuberculosis was especially frequent in lupus cases.

Dr. Radcliffe Crocker said that he admitted the bacillary origin of lupus vulgaris. He had seen lupus even in infancy, and thought that it commenced much more frequently in adult life than was generally supposed, and that adult lupus was almost always of the nodular form. Mr. Clement Lucas related several cases of direct inoculation. One of these was that of an attendant or companion to a lady, who for years had suffered and eventually died from the ravages of lupus. As she dressed her mistress's sores and was constantly with her, it was highly probable that the lupus patch which she exhibited on her nose was contracted from her mistress. Another case in which lupus spread from a wound was that of a policeman, twenty-three years of age. He had received a wound on the knuckle from striking a man in the mouth with his fist, and from this an indurated, crusting, lupus patch spread over the back of his hand. Another man, rather past the middle period of life, injured his forefinger in some machinery, and afterward neglected the wound. Lupus spread all down the forefinger, and gradually over the back of his hand.

A BULLOCK was recently received in England from New South Wales, which some time ago having had one of its hind legs broken at the joint, was provided with a substitute made after the style of the ordinary wooden leg. The bullock has since been able to walk about and to eat comfortably, and has been passed by a veterinary surgeon as being free from pain.

Reports of Societies.

MASSACHUSETTS MEDICAL SOCIETY.
SUFFOLK DISTRICT.
SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

ALBERT N. BLODGETT, M.D., SECRETARY.

In Memoriam.

DAVID HUMPHREYS STORER.

BORN MARCH 27, 1804. DIED SEPTEMBER 10, 1891.

GEORGE HINCKLEY LYMAN.

BORN JULY 17, 1819. DIED AUGUST 19, 1891.

MEETING of January 20, 1892.

In the hall were hung the portrait of Dr. Storer, by Vinton, presented to the Medical Library Association three years ago by his friends in the profession, and a portrait of Dr. Lyman recently presented to the Library Association by his widow.

DR. STORER.

DR. S. L. ABBOT: It is my grateful duty at this time, Mr. Chairman, in response to your call to say a few words in commemoration of the great worth of our departed friend and associate, Dr. David Humphreys Storer. It is eminently proper that this Society should pay its tribute of respect and affection to one who was so highly honored in this community. Secluded as he was for so many of the last years of his life by bodily infirmities, from free communication with his professional brethren, a whole generation of young physicians, members of this Society, has come into active professional life without any personal knowledge of him. It is due to them, if to no others, that the story should be told of his admirable traits and his honorable, useful career.

My acquaintance with Dr. Storer dates back to the very commencement of my professional studies, when I entered as a pupil the Tremont Street Medical School in the early days of that admirable institution. The impression which he gave me at that time remained with me to the end of his life,—that of a warm-hearted, high-toned, conscientious man. There was a cordiality in the grasp of his hand which made you feel at once that he was of a sincere, sympathetic nature. No one realized this more fully than those who were so fortunate as to come under his professional care. He was a skillful, judicious physician, as I early learned from personal experience. In his relations with men he was no respecter of persons; the poor and the rich were both alike to him, and in his large practice all felt that they had the devoted care of a personal friend. He had a high sense of honor and nothing stirred his indignation more quickly than any story of meanness or dishonor. As is common with those of such an ardent temperament his impulsive nature sometimes put him in uncomfortable positions which a man of cooler temper would have avoided. I well remember one instance of this which resulted from his action at a meeting of the Counsellors of the Massachusetts Medical Society, years ago, which had much to do with the expulsion of an unworthy member from the Society. At that meeting, when the conduct

of the offender was under discussion, Dr. Storer took so active a part, that after the expulsion of the member, he was promptly notified that an action for damages to the amount of \$10,000 would be brought against him for defamation of character. But the doctor was not obliged to face the storm alone. The Society at once took up the case and made itself fully responsible for any pecuniary loss which might come to Dr. Storer in consequence. The suit, I believe, was never brought to trial.

Dr. Storer was always a warm friend to young physicians, and personally I was under great obligations to him in my early professional life. It was through his suggestion and influence that I obtained the position of Admitting Physician to the Massachusetts General Hospital. By the gradual expansion of the duties of that office while I held it, the Department of Out-patients grew up, which has developed into such an important addition to the charities of that noble institution, and which was followed in after years by organizations of a similar nature in other hospitals here.

Dr. Storer was a hard worker. He entered into everything which he undertook, with the greatest earnestness. Notwithstanding the pressing demands of a growing practice he found time, as a member of the Biological Commission of Massachusetts, to prepare one of its most valuable contributions to the natural history of the State in his Report on the Fishes. He prosecuted this work with the greatest enthusiasm. The field of study was at that time almost an unexplored one. I well remember the happiness which the acquisition of a hitherto undescribed species brought to him and his eagerness to exhibit it and point out its special features at a meeting of the Boston Society of Natural History. As the result of his labors, besides making a valuable contribution to the science of Ichthyology, he brought together a large amount of material relating to the economic value of our fisheries which makes his report, as a whole, unique, and still keeps it in the front rank of works of its class at the present day.

In conclusion, it is but feeble justice to the memory of Dr. Storer to say that he was a high-toned, honorable man, true to every position of trust and responsibility in which he was placed, and beloved in this community as a warm-hearted, faithful, conscientious physician.

DR. G. J. TOWNSEND, of South Natick, who was not able to be present, sent the following letter:

An uninterrupted friendship of fifty years with Dr. Storer, impels me to offer my tribute to those great qualities of mind and heart, which have endeared him to thousands of friends and patients, have commanded the respect and regard of his brethren in our profession, and have rendered him a power for good in the community, rarely equalled.

My first acquaintance with him was as his pupil, ever earnest and steadfast in the pursuit of knowledge himself, devoting himself unweariedly not only to the study of medicine, but to the collateral sciences, he was ever ready to impart his knowledge to the student, who might thus profit by the practical results of so much time and labor. Dr. Storer was by nature a teacher and to him belongs the credit of originating the Tremont Street Medical School, which, as the germ of the present curriculum of Harvard, has borne such valuable fruit. To his students he was always particularly kind, and I shall never forget his attention

to me, when stricken down in the midst of my studies, by disease of the lungs.

Of Dr. Storer's middle life, others are better qualified to speak than myself, as I saw him only occasionally in consultation, etc., living as I have, a secluded life in the country. But his wise precepts firmly engraven on my mind, have served me in good stead in many a rugged case of midwifery, in regions remote from all available aid, for competent physicians were rare in the early days of my country life. Patience and expectancy up to the proper time for interference, prompt and fearless action when that time came, were his constant instructions. My nurses sometimes tell me that I work over my obstetric cases more than many physicians. Dr. Storer always taught that the very presence of the medical attendant inspires the patient in a lingering case with courage and confidence, thus often enabling nature to terminate a case, without instrumental interference.

His elevation to the chair of obstetrics was a source of great gratification to him, coming, as he has told me, most unexpectedly, — for with characteristic modesty, he had made but little personal effort to obtain it. How successful his teachings in his enlarged sphere were, the well-filled seats in his lecture room abundantly testified.

In Dr. Storer's declining years our relations became more intimate. Passing the summer in my immediate vicinity, it was my good fortune to minister to him and his through many a trying illness. I say good fortune because he was always satisfied with any attention, showed so much confidence in my advice, and was gratified at any little service, out of all manner of proportion it often seemed to me, to its real worth.

A vesical calculus was the final cause of his death. For, though it was crushed and removed by the late Dr. Bigelow, he never entirely recovered from the subsequent cystitis. Very rarely would a word of complaint come from his lips, amidst all his sufferings, and they were many and severe. Once in a while, when in special distress, he would say, "it is confounded hard, Townsend," and I felt that it was hard, that one who had done so much to relieve the sufferings of others, should be so distressed himself.

After the death of his wife to whom he was devotedly attached, life seemed to have lost much of its attraction, but he was always cheerful and most genial to his friends. Full of years and honors, with intellect unclouded to the last, he has passed on the path that none can turn, soothed and enlivened by the devoted care and attention of his children, and hosts of friends. He has left a rare example of faithful work, devotion to duty, and of affectionate regard for his friends, of priceless value. May we all profit by it.

DR. GEORGE C. SHATTUCK wrote as follows:

Yours of the 22d, inviting me to be present at the meeting of the Suffolk District Medical Society, is at hand. My medical adviser says that it is better for me not to accept your kind invitation. My own inclination is to go, for I would gladly bear testimony to the worth and accomplishments of Dr. Storer. I knew him very well, having been his associate for many years in the Massachusetts General Hospital and in the Medical School. He, certainly, was very successful, both as a medical practitioner and as a professor. He had been diligent as a student of medicine and soon acquired a large practice. He had a love of his profession, a zeal and enthusiasm which stood him in

stead, as a practitioner and a teacher. He gained and maintained the respect and confidence of all to whom he ministered. He lived many years in retirement, but maintained his interest in his profession, and had a good and pleasant word to say to all who called on him. He has left an example of conscientious discharge of duty to all who survive him.

DR. O. W. HOLMES sent the following tribute:

I am very sorry that it will not be in my power to attend the meeting at which the memory of our professional brothers, Dr. Storer and Dr. Lyman are to be tenderly and respectfully recalled by those who best knew and who best appreciated their character and their services.

Of these two gentlemen, Dr. Storer was the one with whom I was most closely and longest associated. Soon after I established myself in Boston, an organization known as "The Tremont Medical School" was formed by the association of Dr. Jacob Bigelow, Dr. Edward Reynolds, Dr. David Humphreys Storer and myself. We were not all young, but we were all enthusiastic, sanguine, light-hearted, confident of success. Certainly I had every reason to think myself sure of doing well in connection with such colleagues as these three gentlemen — Dr. Bigelow, leading practitioner, a man of exceptional ability and acquirements, sagacious, prudent, eminently practical in all his ways, the central figure of the group; Dr. Reynolds, full of good-nature, ready to join in every forward movement, producing in the little band of teachers much the same benevolent sense of happy companionship that President Kirkland carried with him into the larger meetings of the University Instructors; and Dr. Storer, whose contagious enthusiasm never admitted for a moment that the Tremont Medical School could be anything but a success, which it eminently proved itself. It was a nursery of professors, all its teachers becoming, sooner or later, members of the Medical Faculty of the University.

In my very brief note to the Natural History Society, I mentioned the peculiar personal interest which Dr. Storer took in the students. He, more than any of his colleagues, carried out the old idea of the Hippocratic oath, which made the relation of medical teacher and pupil almost like that of father and son. The warm cordiality of his manner and the impulsive heartiness with which he entered into their plans and their feelings, kept him in nearer intimacy with the younger scholars than any of us could claim.

Of Dr. Storer's eminence in the specialty to which he was largely devoted, his fellow-practitioners can speak with authority and bear ample testimony. Of his accomplishments as a student of natural history, his accuracy as an observer, his faithful work in ichthyology he has left abundant record. He lived a long, busy, useful and honored life, and to many whom he leaves behind him the world seems colder since his warm heart ceased beating.

DR. A. D. SINCLAIR spoke feelingly as follows: We have assembled this evening to commemorate the life of the late David Humphreys Storer. I have come hither to lay a stone on the cairn to his memory. It is but a feeble expression of the regard in which I held the deceased and now cherish his memory. He was one of my earliest, most respected and beloved masters in medicine; and for a period extending over thirty-seven years, my affection for him remained unchanged. His memory is sweet to me. Dr.

Storer was trusted, honored and beloved by his own profession and the community among which he lived and worked. His patients respected and loved him and for more than half a century his was the prominent name in obstetrics in Massachusetts. Dr. Storer was, moreover, a student of natural science. His contributions to the natural history of Massachusetts will remain a monument to his memory for their accurate and lucid observations. His relations to the world were always transparent and upright. He was a hater of sham and subterfuge; an honest man, one who adorned his profession by his skill, personal dignity, manliness and worth.

DR. G. G. TARRELL said: Since I received an invitation to speak here this evening, I have sought in vain to find adequate words in which to express the feelings of esteem and affection in which I have always held Dr. David Humphreys Storer. Still less has it been possible for me to draw such a picture of his character as to convey to a stranger any idea of the man.

When, in 1862, I was taken by a friend to his house to be introduced, I approached him with that reverence, almost awe, which the newly matriculated medical student always has for the professor and practitioner, then in the very zenith of a successful career. I had heard much about him. I was prepared to respect him, but the straightforwardness of his manner made a great impression upon me, and his frank and genial ways, without a suspicion of affectation, entirely and immediately won me to him. The feeling of respect soon grew to be one of affection, which strengthened from that day until his death. At another Society in this city some description has been given of his scientific attainments. The gentlemen who have preceded me this evening, and the letters from his contemporaries which have been read, do not exaggerate the position which he held in the community. I will leave it still for others to describe many of his strongly marked characteristics. I will attempt no eulogy, nor will I attempt even a sketch, but will occupy the few moments allotted to me in brief mention of one only of the many strong points in his strong character. I refer to his robust, straightforward honesty — his sincerity and singleness of purpose — his absolute and unwavering regard for the truth. His ways were not devious. He went straight for his object, without subterfuge, and he asked the same frankness in others. For errors, for differences of opinion, and for mistakes of judgment, he had the utmost charity. For ignorance, and incompetence, even, he had only pity; but for a wilful misrepresentation, for a concealment of fact, for a partial though plausible statement of a case, he had both anger and withering contempt. And he had the courage of his convictions too. He called a spade a spade. He did not mince matters in his denunciation of untruth, or of the man who knowingly departed by ever so little from the strictest verity. This characteristic brought him occasionally into unfortunate conflict with a professional brother, to his own great grief, but it was with him a matter in which there was no compromise. The other must yield or forfeit his esteem. Yet he was a model consulting physician, giving his opinion boldly, — giving the patient the benefit of the skill on account of which he had been called, — yet doing it in such a way as to bring no discredit upon his younger brother. I know whereof I speak, for I often had occasion to invoke his aid in my younger professional days.

"Faithfully yours" was his usual phrase in signing his letters, — and fully did he keep faith with every one to whom his word was given. Sincerity of purpose was his own high ideal, and by that standard he tried all men. He was unerring in his detection of cant and hypocrisy. Codes of ethics he said were made for thieves, not for an honorable profession; and his own life, not only in its relation to his professional brothers, but with the whole world, was held up to the standard of that earliest and simplest code, "What ye would that men should do to you, do ye even so to them."

DR. A. T. CABOT: Dr. Storer's professional activity ceased before most of us here began the study of medicine. I can only speak from hearsay of his excellent qualities as a teacher, whose enthusiasm inspired his hearers.

You have heard of his professional life from those who were his personal friends during that time, but his scientific interest was not confined within the narrow limits of his profession.

Besides his activity in medicine he was a hard student of natural history, and served as curator and later as vice-president of the Boston Natural History Society. Of the quality of his scientific work you may form some idea if I quote to you the opinion of Mr. Samuel Gorman on Dr. Storer's most important ichthyological publication. Mr. Gorman, who is the assistant in charge of the department of fishes and reptiles at the Museum of Comparative Zoology in Cambridge, says: "The history of the fishes of Massachusetts is a classic in North American ichthyology that must serve as a basis for the future histories of New England fishes." This is high praise and gives us some idea of the untiring zeal of this busy practitioner who thus occupied and enriched his leisure moments.

Leaving now his achievements and coming to the man; it gives me pleasure to recall the genial, kindly presence of my old friend and to speak of those qualities that endeared him to all. He was one of the most sympathetic men I ever knew, and had a genius for cordiality that made a meeting with him an unfailing pleasure. These characteristics were mingled with such courtesy of manner and good feeling that it was easy to see whence came the love and devotion felt for Dr. Storer by his friends and old patients.

Although for many years out of practice he never lost his interest in medical matters, and was keenly alive to every advance. Many interesting talks have I had with him over the progress of abdominal surgery, and he was as much excited over the hopes and fears that ran through the medical community when Koch's material was being tried, as any student could be.

In order that his memory may remain with us I wish to offer the following resolution to be entered in our records:

WHEREAS, Dr. David Humphreys Storer, distinguished for professional and scientific attainments, and endeared to us by kindly, generous qualities of heart and mind has gone from our midst:

Resolved, that while his death has filled us with a sense of personal loss and lasting regret, still we feel that we have reason to be grateful that he was so long spared to live among us, retaining the zeal and enthusiasm of youth to a good old age, and acting as a delightful link between us and the older generations. Realizing the loss to his family and friends we extend them our truest sympathy and share their sorrow.

DR. E. G. CUTLER said: Before the Section takes action on the resolution presented by Dr. Cabot I would like to pay my last tribute of respect to the memory of my medical sponsor Dr. Storer, a genial, kindly, fatherly man for whom I had an affection equal to that of kinship.

His whole scientific and medical life has been most aptly and faithfully portrayed by a distinguished member of our Section before another Society: while the words of those of his fellow-workers and pupils who have preceded me are still echoing in your ears.

As one of the last of the many admitted to his friendship I can only speak of the few last years of his well-rounded life, when at the age of seventy-five, a time when most men say the race for them is run, I found him in the full possession of his faculties and ready to take his share of work as it might come. His interest in and his mastery of the recent medical advances, as already alluded to by Dr. Cabot, were a source of astonishment on first acquaintance and were maintained as long as any strength remained.

A marvel always of punctuality, he frequently told me that during all the long years of his professorship when he was in the midst of a large practice he was never absent from his post of duty once and was only tardy three times.

Dr. Storer was the first Medical Examiner appointed in Boston of the Mutual Benefit Life Insurance Company of New Jersey, and he remained its chief examiner and medical referee for over thirty-five years, and so regular was he in his attendance that he was seated in his accustomed chair daily as the clock ceased striking the hour of twelve.

He was idolized by his many patients and no surer way to their attention was to be obtained than to claim him as an intimate friend.

Ardent, emphatic, outspoken, free of speech, it was a constant wonder that he bore his afflictions so calmly and so patiently to the last.

In his death the young physician has lost his best friend, the profession its most loyal supporter and all of us a most noble example of what the true physician should be.

(The report of that part of the meeting relating to Dr. Lyman will appear in our next issue.)

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

J. C. MUNRO, M.D., SECRETARY.

REGULAR Meeting, Monday, January 4, 1892, DR. S. G. WEBBER in the chair.

DR. WM. M. CONANT read a paper on

IMPERFORATE RECTUM.¹

DR. M. H. RICHARDSON: My experience in cases of imperforate rectum or anus has been limited to three or four. In all the cases there has been, at the usual seat of the anus, at least a dimple, and in most a distinct depression. In most of the cases it has been possible to feel the bulging of the intestine above. In cases of this kind it is of course imperative, in order to save the life of the child, to give exit to the intestinal contents. We all do an operation for this purpose as a matter of routine. In my experience, however, the immediate mortality is very great, and if any con-
